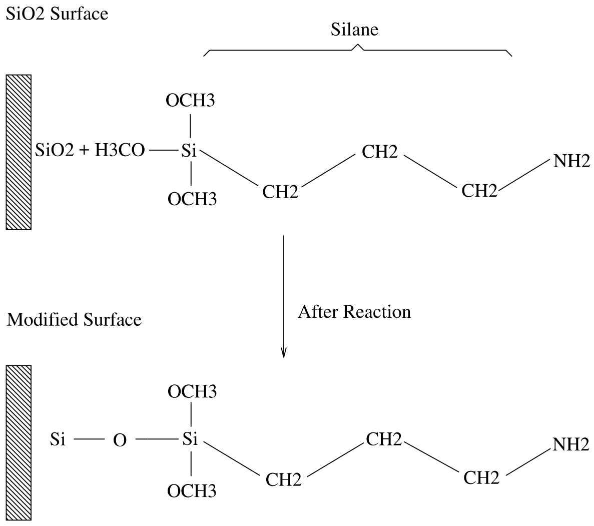
Microfluidic devices have been fabricated from a wide range of materials, such as silicon, fused silica, borosilicate glass, elastomers (poly(dimethylsiloxane) (PDMS)), resins (SU-8), and thermoplastics (poly(methylmethacrylate) (PMMA), polystyrene, polycarbonate (PC), cyclic olefin copolymer, and poly(ethylene terephthalate glycol) (PETG)). The fabrication of glass- or silicon-based devices relies on established technologies such as those of microelectronics and is often considered to be time-consuming and very expensive. Glass, in particular fused silica, is a very attractive material for microfluidic chips owing to its excellent optical properties, good insulating properties, and inertness towards a variety of different solvents. Although silicones have been used mostly as soft-tissue substitutes, serious problems have occurred when silicone devices have been implanted for a long time [1]. In contrast, microfluidic devices fabricated from polymer materials have simpler manufacturing procedures and are cheaper. Furthermore, channels with high aspect ratios are much easier to produce from polymer materials than from glass, which is often advantageous for optical detection.

The surfaces of devices often exhibit different wettability characteristics, depending on the manufacturing approach adopted. Surface modification techniques can be used to alter the wettability behavior of microfluidic devices. This difference in wettability can be used to control the flow rate in devices. There are many other benefits of hydrophilic surface treatments, including the ability to increase adhesion and capillary effects [2]. Irrespective of the material used in the device, the primary requirement that a material needs to fulfill is biocompatibility in various applications. Therefore it is also necessary to use surface modification techniques to render materials biocompatible. It is believed that future devices of increasing sophistication will often require programmable surface properties, including control of the spatial distribution of charge and polarity [3].

Conventional polymers do not always possess the combination of desired bulk and surface properties for a specific application. The polymer materials used for microfluidic devices are innately hydrophobic, low-surface-energy materials and thus do not adhere well to other materials brought into contact with them. This necessitates their surface modification/treatment to render them adhesive. This has prompted the development of a variety of polymer modification techniques, with the aim of developing new materials from known and commercially available polymers that have desirable bulk properties (elasticity, thermal stability, permeability, etc.), in conjunction with newly tailored surface properties (adhesion, biocompatibility, optical reflectivity, etc.).

Currently, the methods used for surface modification of polymers are dynamic coating and permanent surface modification [4]. Dynamic coating is considered to be the easiest way to perform surface modification. In this



Surface Modification, Methods, Figure 1 Surface modification with 3-aminopropyltrimethoxysilane

coating process, surface-active coating materials or surface modifiers are introduced into the buffer, which is then forced through the channel at a constant speed. The coating materials are strongly adsorbed onto the channel surface via physical interactions. Permanent surface modification involves specific chemical reactions which permanently modify the chemical composition of the surface by the application of high-energy sources such as radiation, flames, coronas, plasmas, electron beams, and ion beams to activate the surface before chemical bonding.

For silicon-based microdevices, most of the surface modification approaches rely on silanization chemistry (Fig. 1), where the silanol groups on the surface are derivatized using various silanes. Silica surfaces must typically be coated to effect permanent changes in their properties [3]. A wide variety of techniques have also been developed around surface functionalization using self-assembling monolayers (SAMs) for coatings on silicon surfaces. Monolayers have been deposited on silica surfaces, primarily using chemicals consisting of a hydrocarbon backbone terminating in a polyfunctional alkoxysilyl moiety. Hydrolysis and condensation of these alkoxy groups attaches the hydrocarbon backbone to the silica surface via a siloxane bond. SAMs have been patterned using UV lithography, microcontact printing, scanned-probe lithography, and electron beam lithography. Polymers including polyethylene glycol, polyacrylamide, and hydroxypropylcellulose have been grafted onto silica surfaces using, primarily, methacrylate-terminated intermediates. Successful polymer films prevent both electrostatic and hydrophobic attractions at the wall by presenting an uncharged polar surface to the fluid [3]. Surface modification of silicon-based devices with polyethylene glycol (PEG) can be performed by physical adsorption, covalent immobilization such as grafting and chemical coupling, or gas phase treatment (plasma treatment or deposition) [5]. Although surface modification efforts have proved successful, however, they do not guarantee conformal coating and long-term stability. As in the case of modified PDMS, the surfaces have shown to slowly recover their original hydrophobicity. It is known that an oxidized PDMS surface recovers its hydrophobicity.

Dynamic coating appears to be especially attractive for plastic microchips, as established surface chemistry such as silanization is often not applicable to polymeric materials. Permanent coatings are often regarded as the most effective way to perform surface modification in order to reduce analyte–wall interactions and to modify electroosmotic flow (EOF). Permanent surface modification is, however, often more laborious in the production process and might, accordingly, be less attractive for disposable devices. Dynamic coating methods are applied not only to control EOF and reduce analyte adsorption but also to make a hydrophobic surface more compatible with a hydrophilic separation medium.

Basic Methodology

The chemical modification of the surfaces of polymers is of increasing importance in many diverse aspects of modern technology, with applications which include solid-phase chemical synthesis related to drug discovery, chemical catalysis, biocompatible medical implants and prostheses, diagnostic devices, and surface-modified fabrics, amongst many others. In biological analysis, it is necessary to make polymer surface properties meet requirements regarding wettability, biocompatibility, and nonspecific adsorption [6]. Introducing biological samples, such as plasma or whole blood, into microsystems needs far more consideration of surface modification compared with working with buffer samples of adjusted pH containing cells in the form of polymeric beads. Blood–material contact most often initiates surface-mediated reactions that lead to cell activation and blood clotting.

A wide array of surface modification techniques, ranging from simple to sophisticated, wet to dry, and vacuum to nonvacuum, are available for a host of polymeric materials. They include plasma surface treatment; laser surface treatment; corona, flame, UV, ozone, UV/ozone, photochemical, photografting, chemical-grafting, and chemical methods of surface modification; and modification of polyamide surfaces by microorganisms [7].

S

The surface modification of PDMS is often found to be difficult because the material is inert. Polymer surface modification is required for applications such as biomedical assays, microfuel cells, and lipid-based immunoassay chips. Many surface modifications have been made to PDMS for electrophoretic separation, but new modifications are being made for emerging applications such as heterogeneous immunoassays and cell-based bioassays. These new modification techniques are powerful because they impart biospecificity to the microchannel surfaces and reduce protein adsorption [8]. To decrease the hydrophobicity of PDMS, low-pressure oxygen plasma, UV/ozone, indirect corona, or oxygen-rich butane gas flame treatment is often used to activate the surface and render it hydrophilic. Oxygen plasmas have been the most popular of these techniques. During plasma treatment, the surface of PDMS is subjected to high-energy species, including electrons, photons, ions, and radicals. The surface is oxidized owing to exposure to the plasma and it becomes oxygen-rich and carbon-lean. However, the surface of oxidized PDMS recovers its hydrophobicity after oxidation in a very short time. The recovery in hydrophobicity is caused by the migration of PDMS chains to the surface. It is believed that continuous storage of oxidized PDMS in water stabilizes electroosmotic flow. High-energy treatments make the surface hydrophilic and thus able to support electroosmotic flow; they also helps in the binding of molded PDMS to flat PDMS or other substrates. However, it should be noted that permanent surface modification techniques cannot be directly applied to rigid polymeric materials, owing to the more challenging microfabrication procedures required for those materials.

Some commercially available protein-inert polymers commonly used in microfluidic applications, all of which require permanent surface modification, are polyacrylamide, poly(N-hydroxyethylacrylamide), poly(N,N′-dimethylacrylamide) (PDMA), polyvinylpyrrolidone (PVP), poly(vinyl alcohol) (PVA), hydroxyethylcellulose (HEC), and hydroxypropylmethylcellulose (HPMC). To permanently attach protein-resistant materials to the channel surface, high-energy sources, special chemistries, or even strong physical adsorption have been employed to introduce reactive functionalities. After activation, protein-resistant polymers can be anchored via UV-initiated free-radical polymerization. Polymeric materials usually do not have good solvent and heat resistance compared with inorganic materials, and hence it is necessary to take precautions during surface treatment to avoid serious damage to the microstructure or alteration of the physical properties of the bulk material.

One successful method for PDMS surface modification is ultraviolet polymer grafting. In this method, PDMS is immersed in an aqueous solution of $NaIO_4$, benzyl alcohol, and a monomer (acrylic acid, acrylamide, dimethyl acrylamide, hydroxyethyl acrylamide, or PEG-monomethoxyacrylate) under uniform exposure to a 200 W mercury lamp. $NaIO_4$ scavenges oxygen in the polymerizing mixture, and benzyl alcohol facilitates chain transfer during polymerization. The graft density increases with the irradiation time and also with the concentration of benzyl alcohol. When individual polymers are compared, the highest graft density is achieved with polyacrylamide, whereas the lowest is obtained with poly(PEG-monomethoxyacrylate) [9].

One of the earliest methods for modification of a PMMA surface for medical applications is based on chemical conversion of the wall rather than on addition of a new layer [9]. The conversion of PMMA consists of reesterification of PMMA with polyfunctional hydroxyl compounds, such as ethylene glycol, glycerol, mannitol, or saccharose. First, the PMMA surface is covered with ethylene glycol or another polyalcohol, which is allowed to diffuse inside the polymer body. Then the surface is treated with hot sulfuric acid to perform reesterification and replace the methanol in PMMA with ethylene glycol. After neutralization with sodium bicarbonate, a hydrophilic, transparent layer is formed on the surface of the PMMA.

Polycarbonate is a thermoplastic material used in many applications, including microchips. The aromatic rings in the polycarbonate structure offer a relatively easy way to modify the PC surface by a direct sulfonation reaction. After cleaning with isopropyl alcohol, the polycarbonate surface is modified by reaction with sulfur trioxide at 50°C for 10 min. Then it is rinsed with water and dried in a stream of nitrogen. The sulfonated PC has shown improvement in both surface wettability and electroosmotic mobility. As an alternative to coating the PC surface forming the wall, UV and excimer laser (at a wavelength of 248 nm) treatment of the PC surface have also been used for surface modification. PETG is another plastic material used for the preparation of microchips. Its surface can be modified easily by NaOH treatment, resulting in ester hydrolysis and the appearance of carboxylic groups on the surface.

Dynamic wall coatings for surface modification can be applied to glass substrates owing to the presence of silanol groups on the channel surface. PDMA can be used simultaneously as a sieving matrix and a wall coating for a glass microchip. Several other polymers, including PEG, PVP, HEC, and epoxy poly(dimethyl acrylamide), are applicable as coatings on a glass chip. Several dynamic coatings can be applied to PDMS chips to make the channel surface more hydrophilic. An n-dodecyl-b-D-maltoside

(DDM) coating minimizes protein adsorption on PDMS surfaces [10]. DDM is an alkyl polyglucoside, which belongs to a family of very mild nonionic surfactants. It adsorbs strongly on hydrophobic surfaces and forms a monolayer. This monolayer coverage causes the surface to become hydrophilic and nonionic, thus reducing the interaction between the protein and the surface. Several dynamic coatings have been tried for modifying PMMA surfaces [9] of microchip channels used with 1-aminopyrene-3,6,8-trisulfonate-labeled oligosaccharides. However, low-molecular-weight compounds, including monoethylamine, diethylamine, and triethylamine, and surfactants, such as sodium dodecyl sulfate, cetyltrimethylammonium bromide, and dodecyltrimethylammmonium chloride, do not adequately suppress the adsorption of analytes on the channel wall. A significant improvement is observed when hydrophilic neutral polymers, including PEG, HEC, HPMC, and methylcellulose are applied to PMMA walls.

The surface properties of many materials may be tailored, for example for adhesion promotion, nonstick properties, or chemical activation, by coating with silanes. From a general point of view, silanization of hydroxyl-terminated substrates is an effective and frequently used procedure for modification of the chemical and physical properties of a substrate, as well as for covalent immobilization of a variety of compounds. Surfaces bearing oxides are well known to be of potential interest for chemical modification with silanes. Silane coatings serve in a number of applications such as protective coatings and adhesion promoters on metal surfaces, adhesives in industrial paints, selectively binding surfaces for tethering biological molecules in biosensor and DNA chip design, scanning probe microscopy (SPM) studies of biomolecules, and chemical force microscopy studies (where they serve as probe-functionalizing agents). Silanes have also been grafted onto plastic and elastomeric microchannels. Silanes have the general formula $RSiX_3$, where R is an organofunctional group, selected according to the desired surface properties, and X is a hydrolyzable group, typically an alkoxy group, which is capable of reacting with the substrate. The silanes are normally hydrolyzed at some stage in the coating process, allowing interaction with the substrate via either hydrogen bonds or covalent bonds.

The surfaces of glasses contain silanol groups. The presence of silanol groups on the surface of a glass microchip makes reaction with silanol the first choice for modification of glass surfaces. In one approach, after the channels have been flushed with NaOH, the channels are first filled with γ-methacryloxypropyltrimethoxysilane in diluted acetic acid and/or acetonitrile for an hour. In a second step, an aqueous solution of acrylamide together with ammonium persulfate and 1,2-bis-(dimethylamino)ethane (TEMED) is then pumped into the channels and polymerized at room temperature. The channels are then flushed with water and dried under vacuum. In another approach, channels in borofloat glass chips are coated with thermally immobilized PVA. A 1% aqueous solution of PVA is repeatedly pumped into the channels, and then the channels are emptied by a nitrogen flow. The chip is flushed with a nitrogen flow at 70°C for 60 min, followed by heating at 160°C for 10 min without any flow.

Chemical modification of microchip surfaces with SAMs has been used to prevent or minimize the deposition of proteins on channels. SAMs are ordered molecular assemblies that are formed spontaneously by the adsorption of a surfactant with a specific affinity of its headgroup to a substrate. Immersing an oxidized silicon wafer in a solution of an organosilicon derivative forms the SAM. The formation of a compact monolayer results in a drastic reduction of the surface wettability.

Measurement Techniques

In order to understand the behavior of surfaces after surface modification, it is essential to examine their surface composition and structure in detail. A large number of techniques are available, and it is often desirable to combine several of these methods. The techniques used to monitor surface properties include scanning electron microscopy (SEM), optical profilometry, atomic force microscopy (AFM), X-ray photoelectron spectroscopy (XPS), infrared (IR) spectroscopy, imaging ellipsometry, and water contact angle measurements.

SEM is a tool for measuring surface topography and morphology. SEM functions by focusing and scanning a relatively high-energy electron beam (usually 15 – 30 keV) on a electrically conducting specimen. The measurement of nonconducting samples is difficult owing to charging effects. Often, the sample preparation step introduces difficulties. Transmission electron microscopy (TEM) or scanning transmission electron microscopy (STEM) can also be employed in surface characterization.

Optical profilometry equipment is used for the measurement of surface texture, which includes features such as roughness, waviness, and lay. The methods of measurement available can be further classified into contact and noncontact methods, and three-dimensional (area) and two-dimensional (profile) procedures.

AFM is a tool for measuring surface topography on a nanometric scale. The principle is similar to that of contact profilometry with a nanometric tip. AFM has made significant contributions to biomaterials research in areas

dealing with structure, properties, dynamics, and manipulation. Interface phenomena such as protein adsorption, conformational changes, and subsequent interactions with cellular components can be observed with AFM. Study of the mechanisms of these phenomena can help in explaining why a particular surface treatment may exhibit performance superior to another.

The X-ray photoelectron spectroscopy (XPS) technique is used to identify chemical species on the surfaces of materials. XPS uses a monochromatic, low-energy X-ray beam. The interaction between the incident beam and the atoms of the material causes emission of photoelectrons from within a few micrometers of the surface. The kinetic energy of the electrons is measured and provides information about the nature and environment of the atoms in the surface.

Infrared-based techniques are used to identify molecules on the surface. IR radiation is used to excite vibrational modes in molecules in the gas phase or adsorbed on a surface. The transmitted or reflected IR spectrum can be analyzed in a spectrometer. Considerable improvement in the sensitivity can be achieved by use of Fourier transform infrared (FTIR) spectroscopy. Attenuated total reflection (the ATR-FTIR method) inside a crystal (Germanium) of high refractive index can be used to further enhance the surface sensitivity (using the evanescent field).

Ellipsometry is a nondestructive, label-free optical method for determining film thicknesses and optical properties. Imaging ellipsometry combines the power of ellipsometry with microscopy, and has an *x*-*y*-resolution of approximately 1 μm. It measures the change in the polarization state of light reflected off the surface of the film. Fast ellipsometry methods, both single-wavelength and multiwavelength, have been used for monitoring film growth in situ, allowing the precise control of film deposition processes.

The contact angles and surface tension are connected via Young's equation, based on the thermodynamic energy balance at a fluid/solid/fluid interface. At any point on the perimeter of a liquid drop on a solid surface, three surface tension components (solid–liquid, solid–vapor, and liquid–vapor) are balanced and control the wetting behavior. Both static and dynamic (advancing/receding) measurements can be performed.

Key Research Findings

Surface modification using vapor-phase deposition is very promising for some biomedical nanodevices and has advantages over liquid-phase deposition, since the vapor phase has the ability to permeate more efficiently into silicon nanochannels. A vapor-phase deposition system described by Bhushan et al. [11] used conformal fluorosilane self-assembled monolayer films on silicon and PDMS surfaces. Different perfluorosilane films were deposited onto three different substrates: piranha-cleaned silicon, oxygen-plasma-treated silicon, and oxygen-plasma-treated PDMS. The films were characterized by means of a contact angle analyzer for hydrophobicity, an ellipsometer for film thickness, and an atomic force microscope for surface roughness. The surfaces modified by the fluorosilane films consistently exhibited dramatically higher water contact angles and lower adhesive forces than did the unmodified silicon surfaces.

A pulsed UV excimer laser [4] has been used to modify the surface chemistry and surface charge of a previously imprinted microchannel in PMMA, without changing the physical dimensions of the channel. This surface modification technique was used to reduce the band-broadening effects that occur owing to electrokinetic flow in bends. The electroosmotic mobility was shown to increase by an average of 4% with UV-modified surfaces compared with nonmodified surfaces without any change in the channel morphology. UV exposure was demonstrated to spatially modify the surface charge and to create the desired electrokinetic flow profiles, without the use of wall coatings or the need to change the channel dimensions.

PDMS surface modification using graft polymerization of 2-hydroxyethyl methacrylate (HEMA) induced by a CO_2 pulsed laser was demonstrated by Khorasani et al. [1]. The CO_2 pulsed laser generated radicals on the PDMS surface, which react with oxygen to form hydrogen peroxide through hydrogen abstraction from the PDMS chains. The PDMS surface was then graft polymerized with the water-soluble HEMA monomer by thermal cleavage of hydroperoxide groups. In vitro assays showed that the addition of poly(HEMA) to hydrophobic PDMS provided a suitable surface for reducing platelet adhesion and allowed activation of the surface, unlike the unmodified sample. It was also observed that the laser-treated samples without any graft polymerization become almost superhydrophobic, with a contact angle of 170°. It was shown that these superhydrophobic PDMS films had higher blood compatibility than the hydrophilic PDMS and the untreated PDMS.

Photopatterned surface modification has been demonstrated by Kirby et al. [3], for the purpose of arbitrary control of the surface charge and hydrophobicity of silica-based microfluidic structures. The microchannels were globally coated with an acrylate-terminated SAM followed by localized polymerization of polyacrylamide, resulting in photopatterning of the surface charge and polarity. The photopatterning technique enabled the researchers to pattern isolated regions in the device. The

performance of the coating was evaluated by performing zeta potential measurements, cell adhesion studies, and micellar electrokinetic chromatography (MEKC) separation. The tests indicated a reduction in cell adhesion and wall charge. The coatings showed good stability under biological pH conditions, but degraded under extreme pH conditions. It was also shown that the SAM coating protocol had only a marginal effect on the electrokinetic performance of silica microchannels.

PEG chains have been added to polymer substrates as a means of minimizing nonspecific protein adsorption, because of their low interfacial energy, nonadhesive properties, and high mobility. A simple method for the deposition of brush-like PEG chains on PMMA microfluidic channel surfaces was reported by Bi et al. [6]. A copolymer of butyl methacrylate (BMA) and poly(ethylene glycol) methyl ether methacrylate (PEGMA) was synthesized to deposit a dense PEG molecular, brush-like coating on the PMMA microchannel surfaces via the anchoring effect of the hydrophobic BMA units. The addition of hydrophilic PEG chains to microchip surfaces overcomes the limitations caused by the hydrophobicity of PMMA. The modified microchannel surfaces showed good wettability, low nonspecific adsorption, and better biocompatibility, and enhanced the electroosmotic mobility compared with the mobility in the native state. The modified surface also showed excellent blood compatibility, with low protein and platelet adhesion.

Recently, a new method has been developed to modify the hydrophobic and hydrophilic nature of silicon surfaces by the use of 5-(4-Hydroxyphenyl)-10,15,20-tetra(p-tolyl)porphyrin self-assembled monolayers [12]. The bare SiO_2 substrate exhibited a contact angle of $33 \pm 2°$, showing the hydrophilic nature of the surface. In the presence of a hydroxyphenylporphyrin SAM, the contact angle was found to increase to up to $75 \pm 3°$, indicating the hydrophobic nature of the surface due to the formation of a self-assembled monolayer on the SiO_2 surface. Hydrophilic surface modification of PDMS using an atmospheric plasma has recently been reported by Hong et al. [2]. PDMS stamps were shown, by measurement of the water contact angle and XPS and AFM analysis, to exhibit surface hydrophilicity after the plasma treatment.

The hydrophilic stability of surface-modified PDMS was described by Bodas et al. [13]. Three different modification processes, namely conventional oxygen plasma treatment, two-step modification using $O_2 + C_2F_6$, and chemical modification using HEMA, were considered in the study. All of the surfaces were characterized using static contact angle measurements and ATR-FTIR spectroscopy. Oxygen plasma modification resulted in hydrophilic stability for about 2 days. The hydrophobic recovery in this case was due to the migration of low-molecular-weight species from the surface to the bulk of PDMS. HEMA modified PDMS showed the lowest contact angle and retained its hydrophilicity for over 10 days. The wettability in this case was attributed to carbonyl groups. The $(O_2 + C_2F_6)$-modified PDMS did not show a much lower contact angle, but its hydrophilic stability was much higher than that of the O_2-plasma-treated sample. This high stability was attributed to stable, hydrophilic CF groups on the surface.

Future Directions for Research

Surface treatments and surface interactions are the challenges ahead for the research community in relation to the development of advanced, sophisticated microfluidic devices. Surface modification techniques need to be optimized for various applications, and particularly for disposable microfluidic devices. PDMS will be a popular material for future microfluidic devices, and some issues associated with most of the currently employed treatments, such as the hydrophobic recovery of PDMS surfaces, need to be adequately addressed.

SPR

Definition

Surface plasmons are electromagnetic waves that occur at metal/dielectric interfaces. The conditions for exciting these optical modes are extremely sensitive to the dielectric environment very near this interface. As a result, surface plasmon resonance (SPR) is one of the most commonly exploited label free optical biosensing techniques in use today.

Overview

This article introduces the essentials of surface plasmon resonance biosensing. The *Basic Methodology* section focuses on describing the experimental techniques involved and some of the advantages and disadvantages of the various implementations that are in common use today. In the *Key Research Findings* and *Future Directions for Research* sections, the limitations of the current state of the art in SPR biosensing will be discussed in the context of future analytical needs and the promise of other unlabeled biosensing technologies. For more detailed information, readers are referred to some of the recent reviews of the subject by Homola et al. [1].

Basic Methodology

In this section we introduce the most popular surface plasmon resonance biosensing architectures in use today. In each case the operating principle has been outlined and whenever possible the advantages and disadvantage of the given approach have been discussed both in the context of the competing SPR architectures an other biosensing techniques.

Angular Surface Plasmon Resonance Biosensing

The attenuated total reflection surface plasmon resonance (ATR–SPR), approach using the Kertschmann geometry shown in Fig. 1a, represents the most common SPR configuration in use today. In this arrangement, transversely polarized light is incident on a metal/dielectric interface through a coupling prism. Under most conditions the incident light is nearly completely reflected from the surface and very little loss in optical power is observed at the detector (PMT in Fig. 1a. At a particular angle of incidence, θ_{sp}, a momentum matching condition exists and a certain amount of the incident energy is coupled into a surface plasmon mode resulting in a reduction in the reflected power. The incident angle for this plasmon excitation is described by Eq. (1) below,

$$\sin\theta_{sp} = \frac{1}{n_p}\sqrt{\frac{\varepsilon_m(\lambda)\varepsilon_s}{\varepsilon_m(\lambda)+\varepsilon_s}} \qquad (1)$$

where n_p is the refractive index of the prism, $\varepsilon_m(\lambda)$ is the dielectric constant of the metal film which varies as a function of the excitation wavelength, λ, and ε_s which represents the dielectric constant of the sensing layer (see the inset in Fig. 1a for details of the geometric arrangement). At fixed wavelength, ε_m is constant and thus from Eq. (1) it is apparent that θ_{sp} is only a function of the dielectric constant in the sensing region. The plasmon wave decays exponentially into the sensing layer over a spatial distance on the order of a few hundred nanometers and thus only the near field of the sensing region is probed. In the cases of interest here, this metal/dielectric interface consists of a thin metal film deposited either directly on the prism surface or on a microscope slide that is refractive index matched to the prism. Gold is most often used as it is inert to the atmosphere, can be modified by appropriate surface chemistry to provide active sites for bonding of organic molecules, and exhibits a pronounced surface plasmon effect in the visible and near infrared regions of the electromagnetic spectrum. A subtle variation on the above geom-

etry uses a grating coupler to excite a plasmon wave at the interface [2].

In a typical biosensing experiment, the metal layer is functionalized with a series of biorecognition agents (referred to as probes herein) specific to a solution phase target of interest. The addition of these probes to the surface increases the average dielectric constant in the near field of the sensing layer and a change in θ_{sp} is observed. Following functionalization a solution which may or may not contain targets specific to the immobilized biorecognition agents is introduced to the surface (for most commercial systems this is done using some form of microfluidic delivery system). Should the solution contain the compliment to the surface probe, a positive binding event will occur and the average dielectric constant in the sensing layer will further increase and another shift in θ_{sp} will be observed.

ATR–SPR has numerous inherent properties that have made it one of the most popular biosensing techniques in use today. The primary advantage is that it represents a *label free* technique in that since the transduction signal is based on changes in local refractive index, the targets do not require tagging (e. g., a florescent label). Because measurements of θ_{sp} can be made dynamically quantitative information on the reaction kinetics, such as the bioaffinity constants, can also be obtained. In addition ATR–SPR also exhibits extremely high sensitivity compared with other biosensing techniques. Most systems have angular resolutions on the order of 10^{-4} degrees and bound mass sensitivities on the order of $\mathrm{ng/cm^2}$ (nanograms per square centimeter) which correspond to average near field refractive index changes on the order of $\Delta n = 10^{-5}$. As a specific example, for many nucleic acid based biomolecular recognition systems an adsorbed mass on the order of $700\,\mathrm{ng/cm^2}$ is required for an SPR shift of 1 degree. A significant disadvantage of SPR, however is that this sensitivity is strongly dependent on the spatial distance of the added mass from the sensor surface. Since the plasmon decays exponentially into the solution phase, bound mass which is farther away from the surface has an increasingly lesser effect on the average refractive index and results in a smaller shift in the SPR angle. This represents a significant limitation on the types of systems which can be investigated through SPR.

Figure 2 demonstrates the use of the angular SPR method for the detection of cancer antigens in human sera as performed in Campagnolo et al. [3]. In this case the patient sera is being screened for the presence of antibodies specific to the NY–ESO–1 which is a cancer/testis antigen expressed in a number of malignant neoplasms (see the above reference for more details). In these experiments a nickel-nitrilotriacedtic (Ni–NTA) surface chemistry is applied to the gold sensor surface to serve as the immobilization chemistry. When His-tagged NY–ESO–1 antigen is flown over the functionalized surface, a change in the SPR angle, $\Delta\theta_{sp}$, on the order of 1.15° is observed. Introduction of the antigen is done through a simple microfluidic flow cell. Note that this is quantified in the figure axis in units of PU or *Pixel Units* which are equivalent to a change of 0.0038° in the SPR angle. After washing with the run buffer $\Delta\theta_{sp}$ reduces to 0.15° (∼

40 PU) suggesting that some non-specifically absorbed tumor antigen has been removed from the surface, leaving only the chemically immobilized probes. When Sample A (Fig. 2a) is then flown over the surface, a significant increase in the SPR angle is observed indicating the presence of binding between the immobilized antigen and its compliment and suggesting anti-NY–ESO–1 activity within the patient sample. When Sample D (Fig. 2b) is flown over the surface only a slight change in $\Delta\theta_{sp}$ is observed (due to non-specific adsorption) indicating that the sample does not contain any anti-NY–ESO–1 activity.

Spectral Surface Plasmon Resonance Biosensing

A variation on the above approach, termed spectral SPR (e. g., Otsuki et al. [4]), exploits the wavelength dependence of ε_m to interrogate the surface plasmon coupling conditions. This resonant wavelength condition can be determined from Eq. (1) given a knowledge of the incident angle θ_{sp} and the $\varepsilon_m(\lambda)$ relationship. The apparatus is similar to the angular approach described earlier, the only significant difference being that the experiment is conducted at fixed incident angle and a tunable excitation source is used to sweep over the wavelengths of interest as illustrated in Fig. 1b. Alternatively a broadband excitation source could be used and the spectrum of the reflected light is recorded. Analogous to the angular SPR case, by monitoring the change in the resonant wavelength with time, information on the reaction kinetics and bioaffinity constants can also be obtained.

The spectral technique has two advantages over the traditional angular approach: a simplification of the experimental apparatus for multiplexed SPR imaging and increased inherent sensitivity. As described by Otsuki et al. [4], the spectral approach lends itself to imaging based data collection techniques which are more amenable to high throughput screening applications (this is expanded on in the *Key Research Finding* findings section of this article). The latter of these relates to the relatively weak dependence of ε_m on wavelength as outlined in detail by Homola et al. [5]. Despite these advantages, the angular SPR approach is generally preferred to the spectral approach due to added expense of the tunable illumination source or the added complication of extracting the reflected spectrum.

Local Surface Plasmon Resonance Biosensing

As an alternative to the traditional SPR biosensing approaches, local SPR (LSPR) has recently been developed for surface phase geometries. LSPR surfaces comprise of dielectric substrate with arrays of sub-wavelength scale metallic nanoparticle, nanostructure or nanohole features. Localized surface plasmon resonances occur when light is absorbed or scattered by oscillating electric dipoles within those nanostructures. These standing oscillations represent a slightly different mechanism from the propagating surface plasmon polaritons associated with the architectures discussed above, though the term *plasmon resonance* is commonly used to refer to both. When illuminated these surface arrays exhibit a characteristic change in the transmitted or reflected power at a specific resonant wavelength that is strongly dependent on the local dielectric environment. As such binding events are detected by observing the change in this resonant wavelength using a similar technique to the spectral SPR technique described above. Though the specifics are dependent on the geometric properties of the nanostructure, the relationship between the change in the resonant wavelength and the dielectric constant of the surrounding medium is often reported to be close to linearly proportional to the change in refractive index. The well cited characterization study by Haes et al. [6] provides details of the experimental apparatus and a nanosphere lithography technique

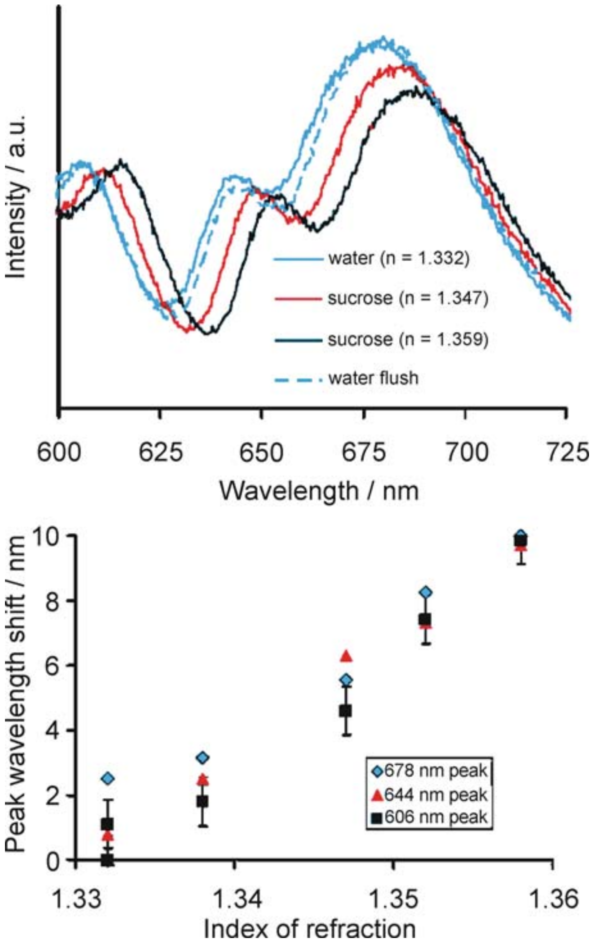
Figure and caption reprinted from De Leebeeck et al. [8]

for surface preparation and functionalization. The sensitivity limits reported in some of the earlier works using this approach were much lower than those for traditional SPR however recently Dahlin et al. [7] described a technique for improving the instrumentation and data analysis techniques for this architecture in the end reporting limits of detection on the order of 100 pg/cm^2. One of the major strengths of the LSPR techniques is that the excitation angle can be normal or near normal to the surface, significantly simplifying the overall setup and facilitating extension to large area two dimensional multiplexing.

As an implementation example of this technique consider the system shown in Fig. 3 which shows a schematic of the optofluidic integration architecture used to couple the microfluidic delivery system with a nanohole array as presented by De Leebeeck et al. [8] . In this case the nanohole array was fabricated in a 100 nm thick gold film on a transparent glass substrate using a focused ion beam milling technique, enabling the creation of feature sizes on the order of 150 nm as shown in Fig. 3b. The plasmonic resonance of each array is governed by the spatial periodicity of the holes. In this experiment, a grouping of nanohole based arrays of varying periodicity constitutes an array of unique SPR sensors. Such a platform could facilitate both a spatial and spectral multiplexed format. The microfluidic chip is fabricated in PDMS using soft lithography and then reversibly bonded to the gold substrate. As shown in Fig. 3a, optical interrogation of the system is accomplished by shining a broadband halogen light source from above and coupling the transmitted light into a fiber spectrometer. In Fig. 4a the transmission spectra obtained with the device through an array of holes with 550 nm periodicity for solutions of varying refractive index are shown. As can be seen the increased refractive index caused by the introduction of the sugar solution cases a red-shift of the transmission spectrum particularly at the $\sim$ 625 nm peak. This is better quantified in Fig. 4b which plots the shift in peak transmission through a 450 nm periodicity nanohole array (which showed three transmission peaks at 604 nm, 644 nm and 674 nm) as a function of the refractive index of the glucose solution. The sensitivity of this device is reported as 333 nm per refractive index unit, or RIU [8].

Solution Phase Nanoparticle LSPR

The final example to consider here is solution phase colloidal nanoparticle LSPR. Such systems comprise of metallic particles (typically spherical, but elongated rods have also been used) dispersed in solution. As with the surface phase LSPR techniques, the nanoparticles are functionalized with a bio-recognition element specific to a target of interest. A sample is then added to the nanoparti-



Surface Plasmon Resonance Sensors, Figure 4 Sample sensitivity measurements using solutions of different refractive indices made using the nanohole SPR device shown in Fig. 2. Transmission spectra were obtained through a 450 nm periodicity array for the cases of pure water, sucrose solutions with increasing refractive index, and again for water. (**a**) Sample transmission spectra plotted together. (**b**) The relative redshift in peak wavelength for three SPR peaks (at wavelengths 606, 644, and 674 nm) exhibited by the array as a function of refractive index. Figure and caption reprinted from De Leebeeck et al. [8]

cle solution and the presence of a positive binding event results in a shift in the measured adsorption peak (for measurements done in transmission mode). Solution phase SPR methods have several advantages over surface phase techniques. The most significant of these being the relative ease with which an assay and be prepared and detection feedback received. Since the assay is carried out in solution, the additional effort required to immobilizing the particles or fabricate structures on the surface directly is not required. With regards to feedback, since the wavelength shifts can, in principle, be quite large it is sometimes possible to detect the presence of a binding event with relatively inexpensive spectrographic equipment (in some cases the shift can even be observed by eye). An additional advantage is that time required for solution phase targets to diffuse to its complementary probe is significantly lower (i. e. the diffusion timescale for a target to reach the nearest nanoparticle is much lower than that required to reach the surface) and therefore the overall reaction time is reduced. The most significant disadvantages of solution phase approach is that multiplexing is a challenge, typically only one reaction can be monitored at a time, and that in general relatively large amounts of target are required in order to ensure relatively uniform binding on all nanoparticles.

The theory which ties the observed macroscopic observation of plasmons to electromagnetics involves an expansion of the involved electromagnetic fields into a series of partial waves to obtain,

$$\sigma_{\text{ext}} = \frac{2\pi}{|k|^2} \sum_{L=1}^{\infty} (2L+1) \times \text{Re}(a_L + b_L) \tag{2a}$$

$$\sigma_{\text{scat}} = \frac{2\pi}{|k|^2} \sum_{L=1}^{\infty} (2L+1) \times (|a_L|^2 + |b_L|^2) \tag{2b}$$

where σ_{ext} and σ_{scat} are the extinction and scattering coefficients respectively, k is the wavenumber and a_L and b_L are the coefficients relating a series of Ricatti–Bessel functions involving particle size, medium refractive index, radius and complex dielectric constant of the particle (see Link and El-Sayed [9] for more details). For smaller particles when the dipole oscillations are dominant, Eq. (2a) can be simplified to,

$$\sigma_{\text{ext}} = \frac{9\omega}{c} \varepsilon_{\text{s}}^{3/2} V \left[\frac{\varepsilon_2}{(\varepsilon_1 + 2\varepsilon_{\text{s}})^2 + (\varepsilon_2)^2} \right] \tag{3}$$

where ω is the angular frequency, ε_{s} is the dielectric constant of the sensing medium, V is the volume, and ε_1 and ε_2 are the real and imaginary components of the dielectric constant of the particle (i. e., $\varepsilon_{\text{particle}} = \varepsilon_1 + i\varepsilon_2$) which are typically functions of ω. Given that ε_2 typically shows a much weaker dependence on ω than ε_1, a maximum in the extinction coefficient occurs when the magnitude of the real part of the dielectric constant of the particle (which is negative for a metal) is double that of the surrounding media.

Future Directions for Research

Though numerous label free refractive index based optical biosensor technologies exist, SPR has evolved as likely the

most popular technique for monitoring surface phase binding reactions largely due to its relatively good inherent sensitivity and ease of implementation/use. Since challenges related to reaction specificity and non-specific adsorption are general to all optical biosensors, they will not be discussed in detail here (this is not meant to diminish their importance). Rather we focus here on listing some of the challenges and limitations of the technology itself and outline some of the general trends of current research.

The high sensitivity of many other optical detection technologies relates to the relatively large interaction lengths of the incident excitation field with the sample. As such a large number of binding events are required in order to induce a relatively small overall change in refractive index and rare target identification therefore becomes significantly more difficult. This is to say that while they are very sensitive to bulk measures such as refractive index, the absolute mass sensitivity can be quite poor. In ATR–SPR the reaction site can in principal be as small as the propagation distance of the plasmon wave, which is typically on the order of 20 μm. As reported above most ATR–SPR systems operate with refractive index resolutions on the order of $\Delta n = 10^{-5}$, though values on the order of $\Delta n = 10^{-8}$ have been reported, and limits of detection on the order of ng/cm^2. Given the plasmon propagation distance value listed above a crude estimate for the bulk mass limit of detection for ATR–SPR can be calculated as being on the order of 10 attograms (10×10^{-15} g). The LSPR technologies discussed were largely developed as an attempt to improve on this value since the optical energy is concentrated over a smaller spatial distance, thereby significantly reducing the probed surface area. As such the presence of significantly fewer binding events can have a larger effect on the effective refractive index and by extension the resonance shift. Using single silver nanoparticle Riboh et al. [10] demonstrated wavelengths shifts on the order of 38 nm for adsorption of ~ 100 antibiotin molecules. Extrapolating then it can be argued that, assuming a molecular mass of 150 kDa for antibiotin, the total mass per particle is on the order of 20 zeptograms (2×10^{-17} g). Although the technology for optically probing these ultrasmall systems is reasonably well developed, practical implementation of such low mass limit of detection systems, implies an ability independently functionalize each nanostructure (or at least a small number of them) with different capture agents. One potential way to do this is to increase the spatial distance between nanotructures to the resolution achievable with traditional spotting techniques and then applying a functionalization chemistry specific to the metallic structures and not the base substrate. Increasing this spatial distance however increases the total surface area over which the sample must be delivered. This poses significant reagent delivery techniques in order to ensure that all targets from a sample have the opportunity to be interrogated by each probe site. With traditional transport mechanisms such as diffusive transport or simple microfluidic architectures, the probability of a collision between a given solution phase target and surface bound probe is exceedingly small (for practical time limits). Developing an integrated system which can address this challenge represents a significant challenge.

One limitation of existing SPR devices has been the degree to which the assays could be multiplexed (i. e., with SPR typically only a few reactions are monitored at a time, compared with microarrays where thousands of binding reactions can be monitored in parallel). Relatively recently a number of Commercial SPR biosensor developers have introduced multiplexed versions of their existing platforms (e. g., the Spreeta from Texas Instruments and FlexChip from BIACORE) based on SPR imaging techniques. Of those that which contains the highest degree of parallelity is the FlexCHIP platform. This chip uses a grating coupling mechanisms and a mechanical scanning technique to image as many as 400 reactions over the course of 3 hours (which is still orders of magnitude lower than microarray based assays). In these multiplexed systems however the sensitivity is reduced to that available from a standard microarray (see Usui-Aoki et al. [11]). As such there remains a significant need for the development of platforms which can maintain the extreme sensitivity available from SPR while pushing the limits of parallelity into the 1000 s or tens of 1000 s of binding reactions.

Definition

Surface roughness measurement is the measurement of the small-scale variations in the height of a physical surface. This is in contrast to larger scale variations such as form and waviness which are typically part of the geometry of the surface.

Overview

In recent years the importance of surface texture has gained attention in many fields. In particular the surface roughness is an important factor in determining the satisfactory performance of a workpiece in areas as diverse as tribology, surface coatings, microfluidics and biocompatibility.

Surface roughness measurement can be characterized using either quantitative or qualitative methods. Qualitative techniques include optical appearance such as the reflectivity of a surface or the strength of the machining lay as well as dragging a thumbnail across the surface as a crude tactile sensor. Quantitative analysis has evolved from simple two-dimensional profilometry to more advanced three-dimensional area analysis where information regarding surface structure can be easily obtained.

The two-dimensional quantitative approach has been in existence since the early 1930s when the need to better understand the manufacturing process necessitated the desire to characterize the surface. More recently, with the advances in computing and data storage, three-dimensional quantitative analysis has gained popularity. Three-dimensional measurement is more suited for non-contact measurement techniques due to the speed of data acquisition.

Basic Methodology

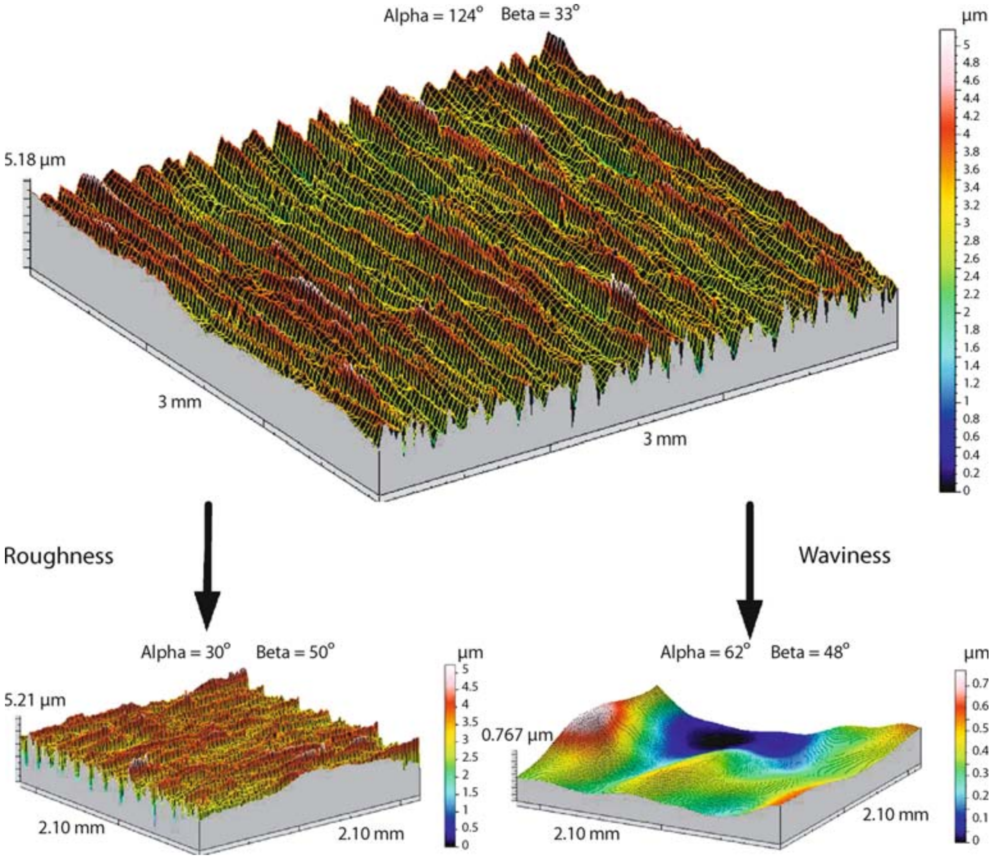
In order to quantify a surface profile, it is essential to remove the unnecessary wavelength components as well as establish a datum from which the parameters can be calculated.

Cut-Off and Filtering

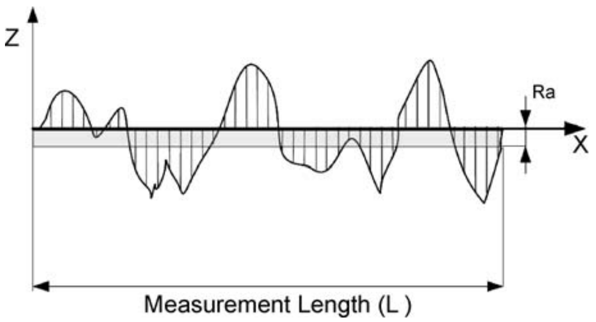
Typically, a surface consists of many wavelengths all superimposed on each other. The wavelengths are generally classified into three groups, form, waviness and roughness, with the last mentioned being the shortest wavelengths and the first mentioned being the longest. To separate the waviness and form from the roughness, a cut-off filter is employed. Depending on which information is to be retained it is possible to select from high- or low-pass filters as well as a band-pass filter which extracts surface data within a specified bandwidth. The selection of cut-off length is laid down in international standards [1, 2].

A number of filter types have been used over the years, each having its own unique frequency response. The oldest standard filter is the 2RC filter and consists of two sets of a resistor and capacitor in series; however, it is subject to large errors when the surface profile direction changes abruptly. It has now been replaced with digital filters which no longer have to rely on physical components. The most common digital filters are the phase-correct 2RC filter and the Gaussian filter – the latter applies a weighting function to the surface data to establish the profile mean line.

Once the surface data have been filtered and the mean line (or plane in the case of three-dimensional measurements) has been determined it is possible to quantify the surface features. Figure 1 shows a ground surface separated into the roughness and waviness components after applying a Gaussian filter and a 0.8 mm cut-off length.



Surface Roughness Measurement, Figure 1 A ground surface being separated into its respective roughness and waviness components after application of a Gaussian filter and a 0.8 mm cut-off length, note the loss of area due to the filtering window



Surface Roughness Measurement, Figure 2 The graphical definition of R_a where the absolute height variations from the mean line are summed

The oldest and most commonly used surface parameter is the average roughness (R_a) which is also known as arithmetic average (AA) and centre line average (CLA) and more mathematically as the arithmetical mean deviation of the profile. The average roughness is the area between the roughness profile and its mean line, or the integral of the absolute value of the roughness profile height over the evaluation length, as shown in Fig. 2 and defined in Eq. (1):

$$R_a = \frac{1}{L}\int_0^L \left|Z(x)\right| \mathrm{d}x \quad (1)$$

However, the main limitation of R_a is that it provides no information about the surface shape; for example, a surface with a regular triangular wave profile could have the same R_a value as a random surface. Over the years, a considerable array of parameters has been developed to provide greater insight into the surface and its function. These parameters are typically grouped depending on what surface attribute they are concerned with such as height or spatial features or a combination of both (hybrid). An additional group which is derived from the amplitude distribution function of the profile provides information regarding the surface shape and its sharpness.

Table 1 provides a list of some of the more commonly used surface parameters with the appropriate standards as reference. The *R* prefix is used for parameters based on the roughness component of the surface while *P* refers to the original unfiltered profile and *W* is the waviness component.

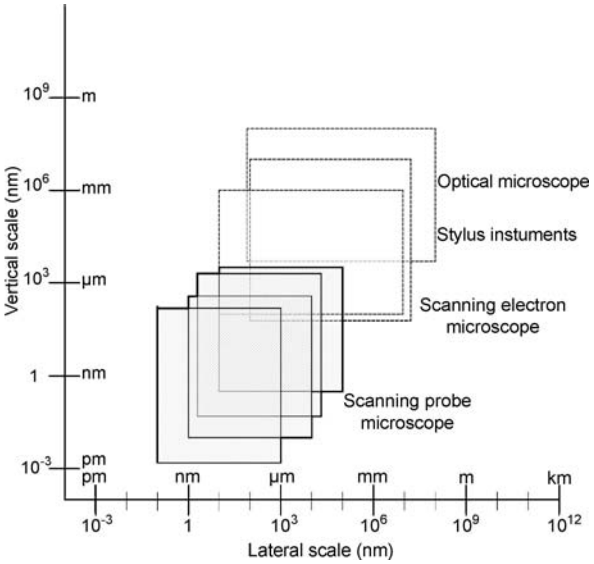
For areal parameters, the main difference is that the reference datum is based on a mean plane and all parameters are calculated from that. The prefix *S* is used to denote these parameters and to distinguish them from the *R*, *P* and *W* prefixes used for profile measurement. A number of the areal parameters are direct three-dimensional equivalents of their profile counterparts such as $S_q(R_q)$ and $S_{ku}(R_{ku})$ while others take advantage of the structural information available to determine the texture direction of the surface and the strength of the surface lay.

Although the application of a single parameter for surface roughness can be used to indicate a change in a manufacturing process, it is not sufficiently discriminating to pinpoint where the changes in the process have occurred. Using an array of simple parameters rather than just one may still not provide the level of discrimination required. With the development of random process analysis, new capabilities arose with the use of autocorrelation and power spectra functions. These are functions rather than numbers such as the average roughness (R_a) of the profile and so can reveal more of the underlying statistics of the surface. The autocorrelation function is particularly useful for looking at random surfaces and the power spectrum is more useful for looking at periodic surfaces. The autocorrelation function is obtained by simply plotting the correlation coefficient between the surface profile and the same profile shifted in space by a set amount. The power spectrum is the Fourier transform of this.

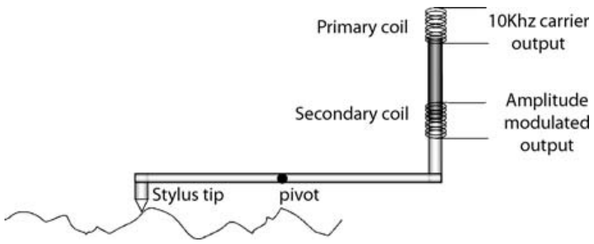
Instrumentation

The earliest ways of measuring surfaces were by using the thumbnail as a tactile sensor or the eyes. Both techniques are highly effective but are completely subjective. Demand for quantitative results led to the development of two distinct branches of instrumentation, one following the tactile approach the other mimicking the eyes.

Both techniques evolved to measure different surface features. Optical methods looked for lateral structure, namely spatial information, whereas contact methods examined heights in the plane perpendicular to the surface. More recently, optical techniques have been developed which can provide height information as well. A more general form of categorization would be to classify the instruments as either contact or non-contact. The lateral and vertical resolutions of the various contact and non-contact techniques are shown in Fig. 3.



Surface Roughness Measurement, Figure 3 Lateral and vertical measurement ranges of various microscopes



Surface Roughness Measurement, Figure 4 Schematic of an inductance transducer-based stylus

Contact Instruments

The contact method involves the dragging of a diamond stylus whose tip dimension is such that it can penetrate the detailed geometry of the surface. The stylus is mounted onto an arm with a transducer at the other end as shown in Fig. 4. Any change in height of the stylus due to the surface features corresponds to a change in the signal detected and amplified by the transducer and the subsequent electronics. The most common type of transducer is based on the inductance principle and offers a large range-to-resolution as well as being of robust construction.

The main limitation of the stylus approach is the need for contact to be made between the probe and the surface which deems it unsuitable for soft materials and where contamination may be an issue. The actual tip dimensions

Surface Roughness Measurement, Table 1 Common 2D surface parameters

Parameter	Name	Standards	Related
	Height Parameters		
Ra	Roughness average (Ra)	1, 2	Pa, Wa
Rq	Root mean square (RMS) roughness	1, 2	Pq, Wq
Rt	Maximum height of the profile	1, 2	Pt, Wt
Rpm	Average maximum profile peak height	1	
Rz	Average maximum height of the profile	1, 2	Pz, Wz, Rtm
Rc	Mean height of profile irregularities	2	Pc, Wc
Rz(iso)	Roughness height	2	
Wt, W	Waviness weight	1, 2	Rt, Pt
	Spacing Parameters		
Sm, RSm	Mean spacing of profile irregularities	1, 2	PSm, WSm
Pc	Peak count (peak density)	1	
HSC	High spot count		
	Hybrid Parameters		
Δa	Average absolute slope	1, 2	$P\Delta a$, $W\Delta a$
Δq	Root mean square (RMS) slope	1, 2	$P\Delta q$, $W\Delta q$
	Amplitude Distribution Function Parameters		
Rsk, Sk	Skewness	1, 2	Psk, Wsk
Rku	Kurtosis	1, 2	Pku, Wku

also act as mechanical filter removing features smaller than the tip radius from the measurements.

Non-Contact Instrumentation

A wide range of techniques can be used to capture the surface roughness of a component using non-contact methods. Some of the more common instruments used to capture topographic data include confocal microscopy, laser triangulation, focus detection and optical interferometry. A relatively recent branch of microscopy known as scanning probe microscopy (SPM) yields over 20 other instruments which are defined based on what probe–surface interaction they are monitoring. The SPM family is described in more detail elsewhere in this book and will be briefly mentioned in this article.

Confocal Laser Scanning Microscopy

Confocal laser scanning microscopy is a valuable tool for obtaining high-resolution surface images as well as enabling three-dimensional reconstruction of the surface. In contrast to a conventional optical microscope which floods the entire specimen with light, confocal microscopy relies on point illumination. A pinhole in an optically conjugate plane in front of the detector ensures that out-of-focus information is eliminated and thus only light within the focal plane is detected resulting in a much higher quality image. As only one point is illuminated at a time in confocal microscopy, two- or three-dimensional imaging requires scanning over a regular raster (i. e. a rectangular pattern of parallel scanning lines) in the specimen. The thickness of the focal plane is defined mostly by the square of the numerical aperture of the objective lens, and also by the optical properties of the specimen and the ambient index of refraction. This technique has found widespread use for biological and semiconductor applications.

Focus Detection System

The optical focus system or optical profilometer system is based on the dynamic focusing principle of a confocal microscope. These systems work on the detection of the focus position of reflected light from the surface. Any change in the focus position of the light relates to a change in the surface height and by refocusing the lens it is possible to determine the height value. It is widely used in applications where surface damage is an issue for concern.

Optical Interferometry

Optical interferometers work on the principle of exposing the surface to be characterized to monochromatic or white light and observing the interference fringes pro-

duced using an optical flat tilted through a small angle. The fringe patterns are produced by splitting the light beam and the interference patterns are produced due to interference between reflections from the tilted optical flat and the surface to be measured. The fringe patterns are analyzed by a computer program incorporating the appropriate algorithms to give an unfiltered representation of the surface. The data may be statistically processed and filtered to provide parametric values.

Laser Triangulation

The principle of laser triangulation is essentially the measurement of range by location of three points forming a triangle. A laser spot is focused onto the sample surface, and as the surface height changes, the position of the reflected beam onto a position-sensitive detector is also shifted. This shift in the reflected beam can, using the triangulation principle, be related back to the surface height deviation.
As with most optical-based systems, a number of limitations exist which include the need for the specimen to possess some degree of reflectivity, a limitation on the maximum surface slope which can be detected and the effect of surface color change on the fidelity of the data.

Scanning Probe Microscopy

Scanning probe microscopy is a branch of microscopy that forms images using a physical probe that scans the surface of the specimen. An image is obtained by mechanically moving the probe in a raster scan of the specimen, line by line, and recording the interaction between the probe and the surface as a function of the position. A wide range of interactions can be observed depending on which phenomenon is being observed; they include atomic force, tunnel current, magnetic force and electrostatic force.

Future Directions for Research

Current research in surface roughness measurement is directed at both the hardware and the software. Established filtering techniques such as Gaussian filtering do not satisfy all applications and research is currently being undertaken to develop filters based on the wavelet principle. Instrumentation is currently being developed to overcome the limitations of current contact and non-contact techniques such as, for example, measuring the sidewalls of a microchannel. This has led to the development of more specialized probes which can sense topographic changes in more than one direction at the same time.

Surface Tension, Capillarity and Contact Angle

KAMRAN MOHSENI
Department of Aerospace Engineering Sciences,
University of Colorado, Boulder, CO, USA
mohseni@colorado.edu

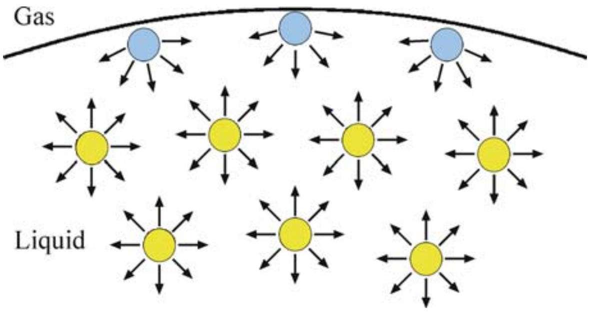
Overview

Surface tension is important in daily life and many engineering applications. Surface tension plays a major role in many applications such as washing and cleaning procedures, in lubricants such as those used in automobiles and cosmetics, and the formation of rain drops. It is even the phenomenon that allows the water-strider to walk on water. This introductory review presents some of the basic concepts associated with surface tension and capillarity. First, we consider the mechanical and thermodynamic definition of surface tension. This is followed by capillarity, contact angle, governing interface equations, relevant nondimensional numbers with surface tension effects, capillarity rise, temperature and surfactant effects of surface tension, and dynamic contact angles. Techniques for measuring surface tension and contact angle then follow. Controlling the wettability of a surface is then presented in order to create surfaces with superhydrophobic properties. Example applications of surface tension and capillarity are briefly presented at the end.

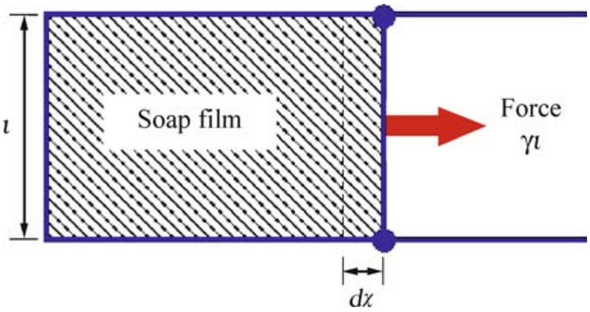
Chemical and Physical Principles

Surface Tension

Surface tension, often represented by σ or γ, is a property of liquids arising from an imbalance in molecular cohesive forces at the surface of the liquid (see Fig. 1). The attractive forces between molecules of a liquid are often stronger than forces between the liquid molecules and the surrounding gas or another immiscible liquid. In the bulk of a liquid each molecule is pulled equally, on average,



Surface Tension, Capillarity and Contact Angle, Figure 1 Adhesive and cohesive forces on molecules of a liquid close to an interface and away from it



Surface Tension, Capillarity and Contact Angle, Figure 2 Surface tension can be considered as the work required for creating a unit surface area. In this case, the work is equal to $\gamma\delta S$ for a force equal to γl and moving a distance dx. The increment in surface area is $\delta S = l\,\mathrm{d}x$

in all directions by neighboring liquid molecules, resulting in a net zero force. However, the situation is different at the surface of the liquid where the liquid molecules are pulled more effectively by other liquid molecules, resulting in a net inward force. As a result of higher molecular attraction between the molecules of the same liquid than the attraction to molecules of another fluid, the surface of the liquid tends to contract inward. This net inward force can be mechanically modeled by assuming an apparent elastic surface under tension. In this case, the force per unit length along the interface between the two immiscible fluids is called surface tension. Surface tension can also be interpreted as the storage of energy at the surface of a liquid: energy per unit area. Therefore, γ is the work required to create a unit area of interface (see Fig. 2). This is a more thermodynamic definition for surface tension. In this case, in order to increase the surface area of a liquid by δS, an amount of work equal to $\gamma\delta S$ is required. The SI units for surface tension are N/m (force per length) or J/m^2 (energy per area).

Water at 20° has a surface tension of 72.9 mN/m in contact with air compared with 35 mN/m for SAE 30 oil and

Surface Tension, Capillarity and Contact Angle, Table 1 Surface tension values for some common liquids at 20 °C

Interface	Surface tension (mN/m)

486.5 mN/m for mercury. Surface tension values of common liquids are listed in Table 1.

Contact Point and Line

The line that delimits the wetted portion of a surface by a liquid is called the contact line. In two-dimensional flows the contact line reduces to a point (see Fig. 3). For a static droplet, the angle of the interface between the liquid and the solid surface is called the static contact angle θ.

Capillarity

Capillary actions or capillarity is a scientific topic concerning the equilibrium shape of interfaces in contact with a solid wall; in particular, in thin tubes or capillaries. For instance, for water in a thin glass tube, the strong hydrogen-bonding interactions between the water molecules and air at the surface of the glass causes the water to climb up in the tube. These new intermolecular interactions must balance the gravity and the weight of the water column. As a result, since the weight of water in a narrow tube is less than that in a thicker one, the water will climb higher in a narrow tube. The

curved free surface of the liquid in a capillary is called the meniscus.

Capillary action has major biological and engineering implications. For example, capillary actions are responsible for providing nutrients and oxygen and removing wastes and carbon dioxide from cells wherever blood flow is available. It is also the mechanism which distributes water and nutrients from plant roots to plant tissue.

Hydrophobic and Hydrophilic Surfaces

The strength of the capillary effect can be quantified by the contact angle. The rise or fall of a liquid in a small-diameter tube inserted into a liquid pool can be determined by the value of the contact angle. The contact angle for water in a glass tube is less than 90° (wetting the wall) and is more than 90° for mercury in a glass tube. In general, a nonwettable surface where the contact angle is greater than 90° is termed hydrophobic. Conversely, a contact angle less than 90° characterizes a wettable or hydrophilic surface. Surfaces with contact angles greater than 150° are called superhydrophobic. This is sometimes referred to as the "lotus effect" after the self-cleaning property of lotus plants. Water droplets roll off the leaves and cannot make them wet.

Key Research Findings

Young's Equation

The contact angle, as seen in Fig. 3, is set by the balance of surface tension forces in the horizontal direction

$$\gamma_{\mathrm{LG}} \cos\theta = \gamma_{\mathrm{SG}} - \gamma_{\mathrm{SL}} \,. \tag{1}$$

This is known as Young's equation where γ_{LG}, γ_{SG}, and γ_{SL} are the surface tension between the liquid and gas, solid and gas, and solid and liquid respectively. Young's angle is a result of thermodynamic equilibrium of the free energy at the contact point. This equation was derived by Young in 1805 shortly before its independent publication by Laplace. The same equation was also derived by Gibbs in 1906 through an energy minimization approach. By using Young's equation one can define a wetting coefficient k as

$$k = \frac{\gamma_{\mathrm{SG}} - \gamma_{\mathrm{SL}}}{\gamma_{\mathrm{LG}}} = \cos\theta \,. \tag{2}$$

Note that k has a value between 1 and -1. For hydrophilic surfaces $0 < k < 1$ or equivalently $0 < \theta < \pi/2$ and the solid is said to be wetted by the liquid. For hydrophobic surfaces $-1 < k < 0$ or $\pi/2 < \theta < \pi$ and the solid is not wetted by the liquid.

Young–Laplace Equation

A curved interface is an indicator of a pressure jump across the interface with higher pressure on the concave side. This can be easily seen in the case of a spherical droplet or bubble. For example consider the free body diagram of a droplet with radius R cut in half, as depicted in Fig. 4. The uniform surface tension along the circumference of the droplet is balanced by the pressure acting on the projected area πR^2. The balance of forces in the horizontal direction results in $(2\pi R)\gamma = (\pi R^2)\Delta P$, or $\Delta P = P_{\mathrm{i}} - P_{\mathrm{o}} = 2\gamma/R$ where P_{i} and P_{o} are the equilibrium pressure inside and outside of the droplet, respectively. In the case of a bubble, one obtains $\Delta P = P_{\mathrm{i}} - P_{\mathrm{o}} = 4\gamma/R$ since there are two layers of surface tensions: one in contact with the outside gas and one in contact with the gas inside the bubble. This simple relation can be extended to any surface with a mean curvature $\kappa = 1/R_1 + 1/R_2$, where R_1 and R_2 are the principal radii of curvature. The resulting equation is known as the Young–Laplace equation

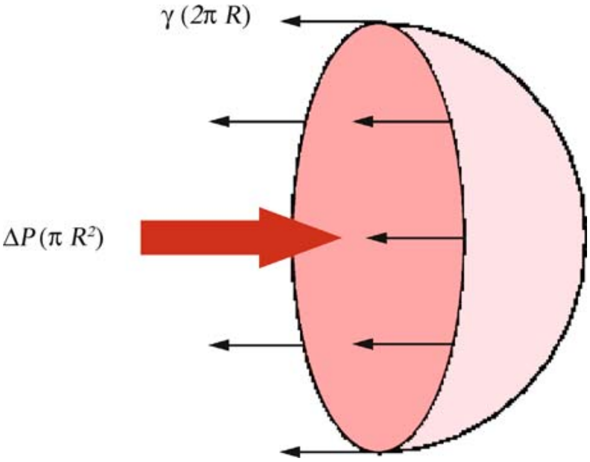
$$\Delta P = \kappa\gamma \,. \tag{3}$$

In the absence of viscous forces, this equation provides a relationship for the change in pressure across a curved interface. It should be noted that pressure jumps across a fluid interface can only sustain normal stress jumps, they do not result in a tangential stress jump. Therefore, tangential surface stresses can only be balanced by viscous stresses associated with fluid motion. Consequently, in the absence of other effects, it is not possible to have a static system in the presence of surface tension gradient. A flow induced by a gradient in the surface tension is called Marangoni flow.

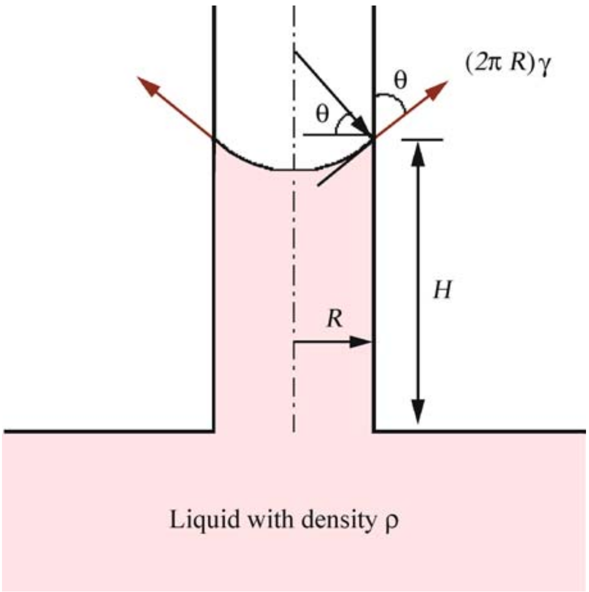
Nondimensional Numbers

Surface tension is a dominant force for liquid handling and actuation at microscales. Surface tension forces scale with a characteristic length scale L as compared with body forces (e. g. gravity) that scale as L^3, and pressure forces that scale as L^2. As a result, modifications of surface tension and other methods with similar scalings are much more effective for microdroplet transport than simple pressure-driven flow.

Consider a fluidic system with surface tension effects. The characteristic scales for length and velocity are L and U. The physical parameters are density ρ, viscosity ν, gravity g, and surface tension γ. By using the Buckingham Π theorem one can obtain three independent nondimensional groups from these six variables. An option for a set of three



Surface Tension, Capillarity and Contact Angle, Figure 4 Free body diagram of forces on a droplet cut in half



Surface Tension, Capillarity and Contact Angle, Figure 5 Capillary rise in a tube. The weight of the liquid column is supported by the vertical component of surface tension forces on the tube wall

independent nondimensional numbers is

$$\mathrm{Re} = \frac{UL}{\nu} = \frac{\text{inertial forces}}{\text{viscous forces}} \tag{4}$$

$$\mathrm{Bo} = \frac{\rho g L^2}{\gamma} = \frac{\text{gravitational forces}}{\text{surface tension forces}} \tag{5}$$

$$\mathrm{Ca} = \frac{\rho \nu U}{\gamma} = \frac{\text{viscous forces}}{\text{surface tension forces}} \tag{6}$$

where Re is the Reynolds number, Bo is the Bond number, and Ca is the capillary number. The Reynolds number expresses the relative magnitude of inertial forces in the system to viscous forces. Transitions from laminar to turbulent flows are characterized by the Reynolds number. The Bond number is a measure of gravitational forces compared to surface tension forces, while the capillary number determines the ratio of viscous forces to surface tension forces.

Two other relevant nondimensional numbers can be defined as

$$\mathrm{We} = \mathrm{Ca} \times \mathrm{Re} = \frac{\rho U^2 L}{\gamma} = \frac{\text{inertial forces}}{\text{surface tension forces}} \tag{7}$$

$$\mathrm{Fr} = \frac{\mathrm{We}}{\mathrm{Bo}} = \frac{U^2}{gL} = \frac{\text{inertial forces}}{\text{gravitational forces}} \tag{8}$$

The Weber number, We, represents an index of the inertial forces to surface tension forces and it is important in analyzing thin films and the formation of bubbles and droplets. The Bond number is often used when considering static surface tension effects, while the Weber number is more relevant in unsteady and moving systems. The Froude number, Fr, compares inertial and gravitational forces. Note that all the nondimensional numbers involving surface tension are boundary-related phenomena and they enter the governing equations through boundary conditions. On the other hand, the Reynolds number is directly introduced through the Navier–Stokes equations.

S

Capillary Rise

The rise or fall of a liquid interface in a capillary can be easily calculated by writing the balance of forces on a cylindrical column of height H (see Fig. 5). The water at the bottom of the tube, leveled with the free surface of the liquid, is at atmospheric pressure. The hydrostatic pressure drop just below the meniscus is balanced by the vertical component of surface tension at the wall. Therefore, $2\pi R\gamma \cos\theta = \rho g(\pi R^2 H)$. Hence, the capillary rise is given by

$$H = \frac{2\gamma}{\rho g R}\cos\theta = 2\frac{\delta_c^2}{R}\cos\theta \tag{9}$$

where $\delta_c = \sqrt{\gamma/\rho g}$ is the capillary length. For nonwetting liquids $\theta > 90°$ which results in a negative H. The capillary length also express the characteristic length of a meniscus; it is determined by the interplay between the Laplace and the hydrostatic pressure across an interface.

Surface Tension Variation

Surface tension values can be affected by temperature change, addition of impurities or surfactants, and, to a lesser extent, by variation in pressure and surface curvature.

Considering that surface tension is the result of cohesive forces between molecules of the same liquid, it would not be surprising to observe that by increasing the temperature (in an other words, by increasing the random kinetic energy of the liquid molecules), the surface tension is decreased. In fact, at the critical temperature, this kinetic energy is enough to break all the cohesive bonds between the liquid molecules and separate the molecules to form a gas.

The surface tension of many liquids decreases, almost linearly, with increasing temperature. In other words, the quantity $d\gamma/dT$ is negative and almost constant for most pure materials. A well-known relation is the Eötvös rule

$$\gamma = V^{-2/3}k(T_c - T) \tag{10}$$

where V is the molar volume, k is a constant equal to 2.1 erg/K for most liquids, and T_c is the critical temperature. Another relationship suggested by van der Waals and further developed by Guggenheim is

$$\frac{\gamma}{\gamma_0} = \left(1 - \frac{T}{T_c}\right)^n \tag{11}$$

where n is a constant equal to 11/9 for most organic liquids but may be closer to unity for most metals, and γ_0 is another constant that depends on the liquid under consideration. Note that in both equations the surface tension approaches zero at the critical temperature.

The surface tension of a material can also be greatly affected by the presence of impurities, particularly surfactants. Surfactants are surface-active agents that contain hydrophilic polar groups on their heads and hydrophobic groups on their tails. As a result, they are soluble in both water and organic solvents. In general, surfactants reduce the surface tension of a liquid. For example, surface tension of water can be greatly reduced by addition of soap or other detergents. This is used in washing processes in order to enable the liquid to penetrate cavities between fibers for more effective washing. Solutes, depending on their structure, can have different effects on surface tension. For example, sugar has no effect on surface tension of water, while inorganic salts increase surface tension, and alcohols decrease it. Surfactants will only decrease surface tension to a set limit and after that they will have no more effect. This can be explained as follows. The equilibrium value of surface tension can be decreased as the number of surfactant molecules accumulating at the surface increases. This process continues until the surface is completely covered by surfactant molecules. At this point, if the surfactant concentration is further increased the extra surfactant molecules will accumulate within the solution and form aggregates; what are called micelles. The concentration of the surfactant at which the surface is completely occupied by surfactant molecules is called the critical micelle formation concentration.

Dynamic Contact Angles

If a droplet is not in static equilibrium, the contact line might move; so too the dynamic contact angles. Figure 6 shows dynamic contact angles for a droplet moving on a inclined plate. Depending on the direction of the liquid movement, different contact angles may be observed. The contact angle measured when the contact line is in movement by wetting the solid is called the advancing contact angle, θ_A. On the other hand, the contact angle observed when the liquid is withdrawn over a pre-wetted surface is called the receding contact angle, θ_R. The advancing contact angle is always larger than or equal to the receding contact angle.

If the contact angle is a function of the speed of the contact line relative to the solid surface, one needs to consider viscous stress forces among other effects. In fact, the viscous stresses show singular behavior at the contact line [1]. The concept of contact line is a continuum concept. This concept breaks down near the surface and one requires molecular considerations in the vicinity of the contact line.

The difference between the advancing (maximum) and receding (minimum) contact angles is called the contact angle hysteresis. Hysteresis can be used to characterize surface heterogeneity, mobility, and roughness. If the sur-

face is not homogeneous, some regions might present a barrier to the movement of the contact line (pinning the contact line) and can be manifested in regions with different contact angles from the surrounding area.

Surface roughness can also generate contact angle hysteresis by actual microscopic variations in the slope of the surface.

Techniques for Measuring Contact Angle and Surface/Interfacial Tension

Correct analysis of capillary and wetting problems requires accurate knowledge of surface tension values and contact angles. In this section we will provide a brief review of methods for measuring surface tension and contact angles. The basic methods for measuring these quantities can be divided into two categories: methods for measuring dynamic quantities and methods for measuring geometrical quantities. Another classification for measuring contact angles of nonporous solids is goniometry and tensiometry. In the goniometry method, the shape of a sessile drop on a solid substrate is analyzed. In the tensiometry method, the interaction forces between a solid in contact with the test liquid are measured.

The Du Nouy Ring Method A ring with perimeter L is immersed in to a liquid and then lifted up. The maximum pull exerted on the ring by the surface tension forces is measured (see Fig. 7a). At the maximum pull the force vector will be exactly parallel to the direction of motion and the contact angle will be zero. The surface tension is then calculated from $\gamma = F_{\mathrm{m}}/L$, where F_{m} is the maximum force during the lift off. A correction for the weight of the volume of liquid lifted beneath the ring could significantly improve the accuracy of this method.

The Wilhelmy Method This is a technique that can be used for both surface/interfacial tension and contact angle measurements (Fig. 7b). To measure the surface tension, a plate with known perimeter P is attached to a balance. The plate is brought into contact with the test liquid and the force due to wetting is measured. The upward force of the surface tension must be equal to the weight of the meniscus measured by the balance. This results in $F = \gamma P \cos\theta$. This equation provides a method to measure the vertical component of surface tension. However, this provides one equation with two parameters: γ and θ. By intensive cleaning or by roughening a platinum plate one could achieve an almost zero contact angle. This results in a single measurement for calculating the surface tension. If the surface tension is known, one can employ the same equation to calculate the contact angle in the same fashion.

Capillary Rise Method In this approach a capillary tube is immersed into the liquid. The surface tension is calculated by measuring the liquid height in the capillary tube via Eq. (9). The capillary rise is also a measure of the vertical component of surface tension.

Tilted Plate Method This is a method for measuring contact angle. In this approach, a plate is immersed in the test liquid until the liquid meniscus becomes horizontal at the point of contact. The contact angle is then equal to the angle of the plate. A tilted plate can also be used for measuring dynamic contact angles. In this case, a plate with a sessile drop on top is slowly tilted until the drop begins to move. At this time, the uphill angle will be the receding contact angle and the downhill angle will be the advancing contact angle. The measurement should be done immediately before the actual droplet motion in order to avoid dynamic effects.

Pendant or Sessile Drop Method The surface tension can be easily measured by analyzing the shape of a drop. This is often done by optical means. Assuming that the drop is axially symmetric and in equilibrium (no viscous and inertial effects) the only effective forces are gravity and surface or interfacial forces. In this case, the Young–Laplace equation relates the shape of the droplet to the pressure jump across the interface. Surface tension is, then, measured by fitting the drop shape to the Young–Laplace equation. Either a pendant or a sessile drop can be used for surface tension measurement. The pendant drop approach is often more accurate than the sessile drop approach since it is easier to satisfy the axisymmetric assumption. Similar techniques can be used for measuring surface tension in a bubble.

Drop Weight Method The drop weight, or Tate's, method is yet another technique for determining surface tension. This approach relies on dripping of a liquid in a gas from a capillary and measuring the combined vol-

umes of the primary and satellite drops that are formed. In this case one can write Tate's law for the weight of the drop

$$\rho g V = 2\pi R \gamma \tag{12}$$

where ρ is liquid density, g is the gravitational acceleration, V is the volume of the drop, and R is the drop radius. By measuring the drop volume and radius one can calculate the surface tension.

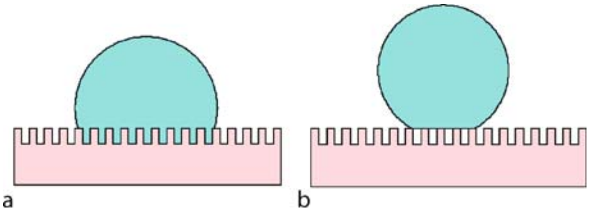
Bubble Pressure or Drop Weight Method In this approach, surface tension is calculated from the measurement of pressure inside the bubble or from the weight of the drop when it detaches from an orifice. The gas bubble can be introduced into a liquid through a capillary with known radius. The maximum pressure p_m during this process is recorded and used to calculate the surface tension. At the maximum pressure, the gas bubble radius is the same as the capillary with the gas bubble forming an exact hemisphere. If the hydrostatic pressure is p_0, and the inner radius of the capillary is R, the surface tension is calculated from the equation

$$\gamma = \frac{p_m - p_0}{2} R \tag{13}$$

After the maximum pressure measurement, the bubble radius increases while the pressure drops. The bubble finally detaches from the capillary and rises to the surface.

Superhydrophobicity

Controlling the wettability of a surface is crucial in many industrial applications. Surfaces with water contact angles above 150° are called superhydrophobic. Such surfaces are important because they could have anti-contamination, anti-sticking, and self-cleaning properties. In nature, superhydrophobic surfaces are observed in lotus leaves, cicada orni wings, and water-strider legs. Water droplets easily roll off such surfaces at a small sliding angle and hereby remove contaminants from the surface.
The high contact angle in superhydrophobic surfaces is often called the apparent contact angle since it does not represent the actual contact angle value of the droplet on a flat surface. The superhydrophobic surfaces are usually covered with micro- or nanoscale roughness. As depicted in Fig. 8 the water can penetrate the gap between the spikes on a surface (Wenzel state) or stay in a suspended state above the spikes (Cassie–Baxter state). In either case a higher contact angle is observed than that observed on a flat surface. In the case where the liquid does not enter the roughness, a drop is supported on a patchwork of solid



Surface Tension, Capillarity and Contact Angle, Figure 8 Effect of surface structures on wetting behavior. (**a**) Wenzel's model where the liquid penetrates between the structures. (**b**) Cassie–Baxter model where water does not wet the surface between the structures

and gas, which leads to very high contact angles. Furthermore, the gas trapped below the drop homogenizes the solid surface and results in very low contact angle hysteresis. Superhydrophobic windshields are nowadays used for better visibility during rain conditions. The water-repellent coated glass enables windshields to shed rain without the need for windshield wipers. If the spatial scale of the roughness is small compared to the wavelength of light the texture does not affect the optical transparency of the windshield.
In the Wenzel model, the apparent contact angle θ_W is obtained by correcting the Young's contact angle θ with a roughness correction factor r

$$\cos\theta_W = r \frac{\gamma_{SG} - \gamma_{SL}}{\gamma_{LG}} . \tag{14}$$

The roughness factor is defined by the actual surface area divided by the projected surface area. Therefore, for a rough surface $r > 1$. Following Wenzel's equation, surface roughness results in enhancing both hydrophobicity and hydrophilicity depending on the nature of the corresponding flat surface. Therefore, for a truly hydrophobic surface $\theta_W > \theta > 90°$ and for a truly hydrophilic surface $\theta_W < \theta < 90°$. For surface roughness factors greater than 1.7, the droplet will have a hard time to wet all the grooves and the system switches from a Wenzel model to a Cassie–Baxter model. In this case, the droplet is suspended on top of the grooves, where the gas is trapped. The apparent contact angle can be calculated from Cassie's law for a liquid on a composite surface

$$\cos\theta_C = f_1 \cos\theta_1 + f_2 \cos\theta_2 \tag{15}$$

where θ_1 is the Young contact angle for component 1 with surface fraction f_1 and θ_2 is the Young contact angle for component 2 with surface fraction f_2. Note that $f_1 + f_2 = 1$. For a two-component system consisting of an air component with a contact angle of 180° the equation is reduced

to

$$\cos\theta_C = f(\cos\theta + 1) - 1 \quad (16)$$

after dropping the second index. This equation implies that it is possible to create surfaces with very large apparent contact angles if the surface has small f and large true contact angle θ. The lotus effect is based on this principle. Note that for a given surface with a true contact angle θ, the apparent contact angle in the Cassie–Baxter model is a function of f only.

Examples of Applications

Some of the industrial applications of surface/interfacial tension and capillarity are: in soil mechanics where the penetration of liquids into porous rocks are considered; in anti-fog, anti-frost, or anti-stain treatment of glass for enhanced visibility in harsh environments; in the chemical industry for uniform spreading of paints, insecticides, ink, and coloring ingredients; in the construction industry for waterproofing of concrete; and in creating fuel spray in internal combustion engines. In the life sciences, locomotion of insects on water surfaces; the rise of sap in plants; adhesion of parasites on wet surfaces; and wetting of eye (an eye is normally wet while the cornea is by nature hydrophobic). Surface tension is also a dominant force at the microscale. To this end, surface tension and its manipulation play a major role in most microfluidic and Lab-on-a-Chip devices. Capillarity is a significant part of capillary liquid chromatography, capillarity electrophoresis, and flow cytometry. Micropipettes work based on the same principle. Surface tension also plays a significant role in applications where the formation of jets and drops are considered.

Further Reading

Some general references for surface and interfacial phenomenon are the books by Adamson and Gast [2] and Hiemenz and Rajagopalan [3]. An interesting scientific background to molecular and macroscopic properties of soap films and bubbles is provided in [4]. The fluid dynamics, heat transfer, and mass transfer of single bubbles, drops, and particles are covered in [5].

Definition

Surface tension driven flow concerns the actuation and control of fluid dynamic transport through a manipulation of the surface tension forces. The manipulation, in principle, can be hydrodynamic, thermal, chemical, electrical or optical in nature. It is also important to mention here that there must be a free surface or a liquid–fluid interface in order to have a surface tension driven flow

Surface tension (γ) is a force per unit length that acts along the interfaces of immiscible phases. For illustration, one may refer to the instance of a liquid–gas interface, the molecules located on which experience a net cohesive force that is directed towards the bulk of the liquid and away from the interface, because of the denser molecular packing in the liquid phase than in the gas phase and a consequent stronger intermolecular force of attraction offered by the liquid molecules. Thus, the interface appears to be in a kind of tension. The interface also must possess necessary energy that overcomes the net attractive force towards the liquid side and allow the interface to sustain. This energy per unit interfacial area is also known as the surface energy.

Overview

It is well known that as the length scale of a system is reduced, surface tension effects become progressively more important, as compared to the other forces that are

S

conventionally dominant over macroscopic length scales. This is primarily because of the fact that the surface tension force scales down only linearly with the length scales whereas most other forces scale down with higher powers of the same. Thus, surface tension, which is a negligibly weak force in the macro domain, may eventually become a dominant force in the micro and nano domains.

From a fluid mechanics viewpoint, the presence of an interface creates a jump in pressure. To appreciate the underlying physical picture from a fundamental viewpoint, let us begin with the thermodynamic description of a liquid droplet in terms of its free energy, as

$$E = \sum_{i \neq j} A_{ij}\gamma_{ij} - \lambda \forall \tag{1}$$

where $\forall$ is the droplet volume and λ is a Lagrange multiplier to enforce a constant volume constraint (physically, λ is equal to the pressure drop across the liquid–vapour interface, thermodynamically consistent with the definition of free energy of a system). Here A_{ij} is the interfacial area that demarcates the phases i and j, with the corresponding surface energy being designated as γ_{ij}. In this article, the subscripts 'l', 's' and 'v' will be employed to represent the liquid, solid and vapour phases, respectively. It can also be noted that if A_{ls} is increased by some amount, A_{sv} is decreased by the same amount. The evaluation of free energy of the droplet, in accordance with Eq. (1), can be best illustrated through the example of a spherical droplet with an equilibrium contact angle θ (refer to Fig. 1 of the article on ▶electrocapillary), for which one can write: $A_{\text{sl}} = \pi R^2 \sin^2\theta$, $A_{\text{lv}} = 2\pi R^2(1-\cos\theta)$, $\forall = \pi R^3\left(\frac{2}{3} - \frac{3}{4}\cos\theta + \frac{\cos 3\theta}{12}\right)$. Thus, for a spherical droplet

$$E = \underbrace{\pi R^2 \sin^2\theta\,(\gamma_{\text{ls}} - \gamma_{\text{sv}}) + \gamma_{\text{lv}} 2\pi R^2(1-\cos\theta)}_{\text{f}} - \lambda\left\{\underbrace{\pi R^3\left(\frac{2}{3} - \frac{3}{4}\cos\theta + \frac{\cos 3\theta}{12}\right)}_{\text{g}} - k\right\} \tag{2}$$

where k is the volume of the droplet. For minimization of E, one must have $\partial E/\partial\theta = 0$ and

$$\frac{\partial E}{\partial R} = 0\,, \quad \text{which implies}$$

$$\frac{\partial f}{\partial \theta}\frac{\partial g}{\partial R} = \frac{\partial f}{\partial R}\frac{\partial g}{\partial \theta}\,. \tag{3}$$

Performing the necessary algebra and simplifying, it follows from Eqs. (3) and (4) that

$$\cos\theta = \frac{\gamma_{\text{sv}} - \gamma_{\text{sl}}}{\gamma_{\text{lv}}}\,. \tag{4}$$

When $0 \leqslant \theta \leqslant 90°$, the liquid is termed as partially wetting, or equivalently, the solid substrate is characterized as hydrophilic. When $\theta > 90°$, the liquid is non-wetting and the substrate is termed as hydrophobic. The case $\theta = 0$, a very special one, represents a theoretically complete wetting. Equation (4), also known as the 'Young's Law', can be interpreted as a balance between the horizontal components of all the forces that act on the 3-phase contact line (refer to Fig. 2 of the article on ▶electrocapillary). The vertical component of this resultant force, on the other hand, is balanced by the normal stress in the rigid solid substrate. Further, substituting the value of $\cos\theta$ from Eq. (4), one may calculate a value of the parameter $\lambda(= \Delta p)$, as

$$\Delta p = \frac{\partial f/\partial\theta}{\partial g/\partial\theta} = \frac{2\gamma_{\text{lv}}}{R}\,. \tag{5}$$

For a droplet of a more general shape, Eq. (5) can be generalized as

$$\Delta p = \gamma_{\text{lv}}\left(\frac{1}{r_1} + \frac{1}{r_2}\right)\,, \tag{6}$$

where r_1 and r_2 are the two principal radii of the curvature of the droplet surface. It is important to note here that the Eqs. (4) and (6) are the two necessary conditions for equilibrium but not sufficient, since in addition, the second variation of E must also be positive for a minimization of the same. In fact, in presence of complex surfaces, certain morphologies may, indeed, result in unstable droplets, even though the necessary conditions of equilibrium are satisfied.

The celebrated Young's equation, as described by (4), is somewhat restricted in nature in a strict sense, since it neglects the bulk internal forces within the droplet that might generate due to gravity, electric field etc. In an effort to generalize the underlying mathematical description, one may note that, for equilibrium of a spherical droplet

$$\mathrm{d}E(R,\theta) = 0\,, \tag{7}$$

which implies

$$\frac{\partial E}{\partial R}\mathrm{d}R + \frac{\partial E}{\partial \theta}\mathrm{d}\theta = 0\,. \tag{7a}$$

Further, since $\forall = \pi R^3\left(\frac{2}{3} - \frac{3}{4}\cos\theta + \frac{\cos 3\theta}{12}\right)$, the condition of $\mathrm{d}\forall = 0$ implies that

$$\mathrm{d}R - Rf_1(\theta)\,\mathrm{d}\theta = 0\,, \tag{8}$$

where

$$f_1(\theta) = \frac{-2\cos^2\frac{\theta}{2}\cot\frac{\theta}{2}}{2+\cot\theta}\,. \tag{8a}$$

Substituting Eq. (8a) in Eq. (7a), one finally gets

$$\frac{\partial E}{\partial R}Rf_1(\theta) + \frac{\partial E}{\partial \theta} = 0\,. \tag{9}$$

Incorporating the effects of gravitational potential energy in the expression for E, one can write

$$E = \underbrace{R^2\left[2\pi\gamma_{\mathrm{lv}}(1-\cos\theta) + \pi\sin^2\theta(\gamma_{\mathrm{ls}} - \gamma_{\mathrm{sv}})\right]}_{\text{contribution from interfacial terms}} + \underbrace{R^4\frac{2\pi}{3}\rho g(3+\cos\theta)\sin^6\left(\frac{\theta}{2}\right)}_{\text{contribution from gravity}}\,. \tag{10}$$

Utilizing the above expression for E in Eq. (9), one can arrive at a more generalized form of the Young equation incorporating gravity effects, as

$$\cos\theta - \frac{\gamma_{\mathrm{sv}} - \gamma_{\mathrm{sl}}}{\gamma_{\mathrm{lv}}} - \frac{\rho g R^2}{\gamma_{\mathrm{lv}}}\left[\frac{\cos\frac{\theta}{3} - \cos 2\theta}{12} - \frac{1}{4}\right] = 0\,. \tag{11}$$

From Eq. (11), following two important observations may be carefully noted:

1. With gravity effects, θ depends on R, unlike the case without gravity.
2. If $\rho g R^2/\gamma_{\mathrm{lv}}$ is small, gravity effects can safely be neglected. This ratio is known as the Bond number (Bo), which essentially compares the square of the system length scale (R) with the square of a characteristic length scale, l_{s}, that depicts the relative contributions of surface tension and gravity influences, as $l_{\mathrm{s}} = \gamma_{\mathrm{lv}}/\rho g$. For Bo $\leqslant 10^{-3}$, gravity effects can safely be neglected, as appropriate to many of the micro-scale transport processes.

The preliminary understanding of pressure jump across a static meniscus with constant surface tension effects (refer to Eq. 6) can be more fundamentally extended to write a generalized expression for the interfacial condition on a mobile phase boundary, as [1]

$$\left[p^{(2)} - p^{(1)} + \gamma\left(\frac{1}{r_1} + \frac{1}{r_2}\right)\right]n_i = \left[\mu^{(2)}\left(\frac{\partial u_i^{(2)}}{\partial x_k} + \frac{\partial u_k^{(2)}}{\partial x_i}\right) - \mu^{(1)}\left(\frac{\partial u_i^{(1)}}{\partial x_k} + \frac{\partial u_k^{(1)}}{\partial x_i}\right)\right] \times n_k - \frac{\partial\gamma}{\partial x_i} \tag{12}$$

where $p^{(1,2)}$, $\mu^{(1,2)}$, $u_i^{(1,2)}$, $u_k^{(1,2)}$ are the pressures, viscosities and velocity components, respectively, in phases 1 and 2, n_i $(i = 1, 2, 3)$ are the components of the unit vector normal to the interfaces and directed into the interior of phase 1, and a summation over the repeated index, k, is assumed. To account for the effects of surface-active elements (surfactants), right hand side of Eq. (12) may be provided with phenomenological source terms of the form

$$-\mu_{\mathrm{s}}\delta_{ik}\frac{\partial^2 u_k^{(s)}}{\partial x_i \partial x_k} \tag{13}$$

where δ_{ik} is the Kronecker delta, $u_k^{(s)}$ are the components of surface motion velocity and μ_{s} is the so-called surface viscosity (a phenomenological constant), which characterizes the dynamical elasticity of the insoluble surface film. In a strict sense, Eq. (13) accounts for the energy dissipation in the surface layer due to irreversibilities associated with the viscous motion of adsorbed particles on the surfaces.

Basic Methodology

Marangoni Effects and Thermocapillary Motion

Fundamental principles associated with surface tension driven flows rely on the motion induced by the variation of surface tension from point to point on a mobile phase boundary, giving rise to tangential strains on the same. According to the boundary condition given by Eq. (12), the presence of tangential strains at the interface is accompanied by fluid motion. Fluid motion induced by the tangential gradients of surface tension is classically known as the Marangoni effect. As an illustration specific to microflow actuations with the aid of thermally-activated surface tension gradients, we consider the steady thermocapillary migration of a gas bubble [2] of fixed volume in a tube of radius a, filled with a liquid of viscosity μ, surface tension γ, density ρ, thermal diffusivity α and temperature coefficient of surface tension $\gamma_{\mathrm{T}} = -\mathrm{d}\gamma/\mathrm{d}T$. Viscosity and the conductivity of the gas are neglected

in comparison to those of the liquid and the length of the bubble is taken to be much larger than the radius of the tube. The temperature gradient imposed on the tube wall is a constant, say β. The variation of interfacial tension as a function of temperature generates a thermocapillary shear stress, inducing the bubble motion at a steady speed towards the hotter region. The liquid is taken to be perfectly wetting. A thin layer of liquid separates the bubble from the tube wall. The three important non-dimensional numbers charecterizing the bubble motion are the Bond number ($\mathrm{Bo} = \rho g a^2/\gamma$), Péclet number ($\mathrm{Pe} = \mathrm{Re}.\mathrm{Pr}$, where Re is the Reynolds number and Pr is the Prandtl number) and capillary number ($\mathrm{Ca} = \mu u_\mathrm{b}/\gamma$), where u_b is the characteristic axial speed of the bubble. For the mathematical analysis, all these non-dimensional numbers are taken to be small. A small Bond number implies that the gravity effects are negligible and the bubble is symmetrically located within the tube. A small Péclet number implies that the advective in the temperature variations are negligible. For small Ca, one can subdivide the flow around the bubble in five different regimes, namely, (I) a section parallel to the wall with constant film thickness (say, b), (II, III) two sections of constant curvature hemispherical caps in the front and in the back, which are connected to the constant film-thickness region through two transient regions at the two ends (IV, V) over which the curvature smoothly varies from zero to a constant value. A small Reynolds number ($\mathrm{Re} = \rho_\mathrm{a} u_\mathrm{b} a/\mu$) assumption allows one to use a lubricating film assumption in the transition regions. With small Capillary numbers, it is also implicit that there are no significant fluid dynamic forces in the regions near the hemispherical caps (since surface tension forces dominate over viscous forces, which in turn dominate over inertia forces for low Reynolds numbers). For the section of the bubble parallel to the wall (section I), one can obtain the maximum velocity at the edge of the thin film of thickness b, analogous to the situation of a shear-driven Couette flow, as

$$U_\mathrm{T} = \frac{\gamma_\mathrm{T}\beta b}{\mu} \tag{14}$$

where the shear stress, τ, is balanced by the Marangoni stress due to temperature gradient (i. e., $\partial\gamma/\partial x = (\partial\gamma/\partial T)(\partial T/\partial x) = -\gamma_\mathrm{T}\beta$). The velocity U_T, however, is unknown, since the film thickness (b) is not known a-priori. In the transition region, the governing equations of fluid flow, in a reference frame fixed with the bubble, can be written as

$$\frac{\partial^2 u}{\partial y^2} = \frac{1}{\mu}\frac{\partial p}{\partial x} \tag{15}$$

subject to the following boundary conditions:

$$u = -U_\mathrm{b} \text{ at } y = 0 \text{ and } \tau = \mu\frac{\partial u}{\partial y} = -\gamma_\mathrm{T}\beta \text{ at } y = h(x) \tag{15a}$$

where u is the liquid velocity in the moving reference frame, x is the axial direction of motion, y is the transverse direction and $h(x)$ is the film thickness. A solution for Eq. (15) can be obtained as

$$u(x, y) = \frac{1}{2\mu}\frac{\partial p}{\partial x}y^2 + \frac{1}{\mu}\left(\frac{\partial\gamma}{\partial x} - \frac{\partial p}{\partial x}h\right)y - U_\mathrm{b}\,. \tag{16}$$

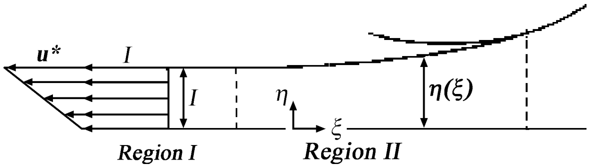
The pressure gradient is related to γ by setting right hand side of Eq. (12) to zero and substituting the expressions of radii of curvature in terms of the geometrical parameters of the surface profile (noting that $\frac{1}{R_1} = \frac{\mathrm{d}^2 h}{\mathrm{d}x^2} / \left[1 + \left(\frac{\mathrm{d}h}{\mathrm{d}x}\right)^2\right]^{\frac{3}{2}}$, where the denominator can be neglected relative to the numerator for small curvature, and $R_2 \to \infty$), one obtains

$$\frac{\partial p}{\partial x} = -\gamma\frac{\mathrm{d}^3 h}{\mathrm{d}x^3}\,. \tag{17}$$

The differential equation for the free surface location can be derived by noting that the flux across any cross section needs to be a constant, which mathematically implies $\int_b^{h(x)} u(x, y)\,\mathrm{d}y = 0$, in the moving reference frame. Also noting that $\frac{\partial p}{\partial x} = 0$ at $y = b$, one can utilize Eq. (16) and (17) to evaluate the above integral and obtain

$$\frac{\gamma}{3\mu}h^3\frac{\mathrm{d}^3 h}{\mathrm{d}x^3} - \frac{\gamma_\mathrm{T}\beta}{2\mu}\left(h^2 - b^2\right) - U_\mathrm{b}(h - b) = 0\,. \tag{18}$$

It is interesting to note that Eq. (18) explicitly takes care of the fact that $h \to b$ when the film becomes flat, or in other words, it takes care of an asymptotic matching of the solution in the constant film-thickness region. For an asymptotic matching with the hemispherical cap, one may use a new set of dimensionless coordinates (refer to Fig. 1)



Surface Tension Driven Flow, Figure 1 Dimensionless coordinates for the description of thermocapillary flow around a liquid–vapour meniscus

such that $\eta = h/b$, $\zeta = x/b\,(3\mathrm{Ca})^{-\frac{1}{3}}$. These rescalings cast Eq. (18) in a modified Landau–Levich form, as

$$\eta^3 \frac{\mathrm{d}^3\eta}{\mathrm{d}\zeta^3} - \frac{U^*}{2}\left(\eta^2 - 1\right) - (\eta - 1) = 0 \tag{19}$$

where $U^* = U_\mathrm{T}/U_\mathrm{b} = \gamma_\mathrm{T}\beta b/\mu U_\mathrm{b}$, which is an unknown parameter. However, given a value of U^*, it is possible to integrate Eq. (19) numerically, with specified sets of initial conditions. When η is very close to unity, Eq. (19) can be linearized to obtain

$$\frac{\mathrm{d}^3\eta}{\mathrm{d}\zeta^3} = \left(1 + U^*\right)(\eta - 1) \tag{20}$$

which has the following general solution [2]:

$$\begin{aligned}\eta &= 1 + A\exp\left(\left(1+U^*\right)\zeta\right)\\ &\quad + B\exp\left(-\frac{1}{2}\left(1+U^*\right)\zeta\right)\cos\left(\frac{\sqrt{3}}{2}\left(1+U^*\right)\zeta\right)\\ &\quad + C\exp\left(-\frac{1}{2}\left(1+U^*\right)\zeta\right)\sin\left(\frac{\sqrt{3}}{2}\left(1+U^*\right)\zeta\right)\end{aligned} \tag{21}$$

where A, B and C are constants of integration. The asymptotic behaviour of the solution as $\eta \to \infty$ can be used by applying the perturbation theory over Eq. (21) to yield [2]

$$\begin{aligned}\eta &= \frac{1}{2}C_0\zeta^2 + C_1\zeta + C_2 - \frac{U^*}{C_0}\left(\zeta\ln|\zeta| - \zeta\right)\\ &\quad + \frac{U^{*2}}{2C_0^3}\ln^2|\zeta| + \left(\frac{U^{*3}}{2C_0^3} - \frac{C_1U^*}{C_0^2}\right)\ln|\zeta|\\ &\quad + O\left(\frac{\ln^2|\zeta|}{\zeta}\right).\end{aligned} \tag{22}$$

The coefficients C_0, C_1 and C_2 are determined from the numerical solution for large values of ζ. The constant C_0 (related to the curvature of the end caps) can be determined as the limiting value of the second derivative for large η. When $U^* = 0$, the asymptotic form simplifies to $C_0 = 0.643$ [2]. In general, C_0 is a monotonically increasing function of U^*, as can be obtained numerically. Another matching condition can be obtained by noting that the mean curvature of the caps equals $2/a$ for the leading order approximation for small Ca, which implies

$$h_{\mathrm{xx}} \approx \frac{1}{a}, \text{ or } \frac{(3\mathrm{Ca})^{\frac{2}{3}}}{b}\eta_{\zeta\zeta} \approx \frac{1}{a}. \tag{23}$$

From the above considerations, one gets

$$\eta_{\zeta\zeta} \approx \frac{b}{a(3\mathrm{Ca})^{\frac{2}{3}}}, \text{ or } C_0\left(U^*\right) \approx \frac{b}{a(3\mathrm{Ca})^{\frac{2}{3}}}. \tag{24}$$

Further, from the considerations of global mass balance, one may note that the rate of volume of fluid pumped by the Marangoni stress, Q_1, must be same as the rate of volume displaced by the moving bubble, Q_2. Since $b \ll a$, one can neglect $O(b/a)$ terms and approximate Q_1 as

$$Q_1 = 2\pi\int_{a-b}^{a} U_T(a-r)r\,\mathrm{d}r \approx \frac{-\pi\gamma_T\beta a}{\mu}\frac{b^2}{a^2}. \tag{25}$$

Similarly,

$$Q_2 = \pi U_b(a-b)^2 \approx \pi U_b a^2. \tag{26}$$

Since $Q_1 = -Q_2$, one may write

$$\mathrm{Ca} = \frac{\mu U_b}{\gamma} = \frac{\gamma_T\beta a}{\gamma}\frac{b^2}{a^2}. \tag{27}$$

Equation (27) can be used with Eq. (24) to express $C_0(U^*)$ as a sole function of b/a, in the asymptotic matching condition. With $C_0(U^*)$ already being obtained numerically, the ratio of b/a can therefore be obtained from Eq. (24), for a given value of $\Delta\gamma^* = \Delta\gamma/\gamma = \gamma_\mathrm{T}\beta a/\gamma$ (which is the ratio of the thermocapillary force to the mean surface tension force). The numerical results can be fitted with the following power law expression [2]:

$$\frac{b}{a} = 13.591\Delta\gamma^{*2} \tag{28a}$$

and

$$\mathrm{Ca} = 184.715\Delta\gamma^{*5}. \tag{28b}$$

One can observe from Eq. (28b) that higher temperature gradients may cause the bubble to move faster. The solutions presented above, however, are rather approximate and are valid for vanishingly small Capillary numbers only.

Electrocapillary Flow

Similar to the thermocapillarity (where temperature gradient creates the driving surface tension force), one can also exploit the effects of electrocapillarity or electrowetting, in which electric potentials can be employed to alter the surface tension and thereby cause a fluid motion. Compared to the thermocapillary flows, electrocapillary flows are much more energy efficient, with a much faster speed

S

of operation (speeds more than 100 mm/s have been successfully achieved by electrowetting action, in contrast to a typical speed of only about 1 mm/s in thermocapillary flows). The electrocapillary principles are all based on the fact that the surface tension occurs to be a strong function of the electrical potential acting across an interface. As a consequence, the apparent contact angle, θ, gets modified from its value at zero voltage, θ_0, in the following form:

$$\cos\theta = \cos\theta_0 + \frac{cV^2}{2\gamma_{lv}} \quad (29)$$

where c is the capacitance of the interface per unit area and V is the interface potential. Based on this fundamental principle, one can design various flow actuating mechanisms such as continuous electrowetting (employing liquid metal droplets in a filler liquid and exploiting the electric double layer potential to alter the liquid/liquid interfacial tension), electrowetting (employing liquid droplets in a vapour medium and exploiting the electric double layer potential to alter the solid/liquid interfacial tension), and electrowetting on dielectrics (employing liquid droplets in a vapour medium and exploiting the potential across a dielectric layer to alter the liquid/liquid interfacial tension), the details of which are outlined in the article on ► electrocapillary. It is important to note here that Eq. (29) can be obtained as a generalization of the Young's equation, by noting that there is an additional electrostatic contribution (E_{el}) to the free energy, which, for the case of electrowetting on dielectrics as an example, can be written as

$$E_{el} = -\frac{1}{2}\frac{\varepsilon_d}{d}V^2 A_{sl} \quad (30)$$

where ε_d is the permittivity of the dielectric layer and d is its thickness. For a spherical droplet, $A_{sl} = \pi R^2 \sin^2\theta$. Thus, the total interfacial energy for this case is given as

$$E(R,\theta) = R^2\left[\pi \sin^2\theta\,(\gamma_{ls} - \gamma_{sv}) - \frac{\varepsilon_d V^2}{2d} + 2\pi\gamma_{lv}(1-\cos\theta)\right]. \quad (31)$$

Minimizing $E(R,\theta)$ for a constant droplet volume, one can arrive at the Young-Lippman equation:

$$\cos\theta = \frac{\gamma_{sv} - \gamma_{sl}}{\gamma_{lv}} - \frac{\varepsilon_d V^2}{2\gamma_{lv} d}. \quad (32)$$

It is important to note here that although fairly general, the above analysis is not strictly valid for apolar liquids (for example, silicone oil at the top of a conducting solid substrate). In such cases, the droplet may be modeled as an insulator with a permittivity of ε_l. The electrical energy stored in that case can be estimated as $1/2\varepsilon_l R^3 (V/R)^2 a_{de}(\theta)$, where $a_{de}(\theta)$is a shape factor, which cannot be computed analytically, but can be numerically fitted as [3]

$$a_{de}(\theta) \approx 0.0592 + 0.0012\theta + 0.0022\tan(1.71-\theta). \quad (33)$$

In this situation, a generalized Young equation can be arrived at by applying the energy minimization principle, to obtain

$$\cos\theta - \frac{\gamma_{sv} - \gamma_{sl}}{\gamma_{lv}} + \frac{\varepsilon_l V^2}{2\gamma_{lv} R}\frac{2+\cos\theta}{2\pi\,\sin\theta} \times \left[a_{de}(\theta) f_1(\theta) + \frac{da_{de}}{d\theta}\right] = 0. \quad (33a)$$

Solutal Gradient Originated Surface Tension Driven Flow

Other than due to the imposed gradients of temperature and electrical potential, surface tension gradients can spontaneously originate as a consequence of droplet splitting or coalescence, mixing of samples or chemical reactions. Typically, surface tension gradients generated during the contact of dissimilar liquids are much larger than those obtained as a consequence of thermocapillary variations. Deposition of biological liquids containing surface active elements onto a liquid film with higher γ_{lv} generates Marangoni stresses, which can cause rapid thinning and rupture of films. For an interface containing surface-active molecules, the surface tension is likely to vary with the local concentration, giving rise to a tangential stress, τ, as

$$\tau = \nabla_s \gamma_{lv} = \left(\frac{d\gamma_{lv}}{d\Gamma}\right)\nabla_s \Gamma \quad (34)$$

where $\Gamma(\boldsymbol{x},t)$ is the surfactant surface-concentration, which is governed by the following advection-diffusion equation:

$$\frac{\partial\Gamma}{\partial t} + \nabla_s \bullet (\Gamma \boldsymbol{u}_s) + \Gamma\,(\nabla_s \bullet \boldsymbol{n})\,(\boldsymbol{u}\bullet\boldsymbol{n}) = D_s \nabla_s^2 \Gamma. \quad (35)$$

The flux of the surfactant depends on the tangential component of the surface velocity, $\boldsymbol{u}_s = \left(\underline{\underline{I}} - \boldsymbol{nn}\right).\boldsymbol{u}$, the mean curvature of the interface, $\nabla_s \bullet \boldsymbol{n}$, and the surfactant surface diffusion coefficient, D_s. Soluble surfactants require

the specification of the interfacial adsorption/desorption kinetics relating the surface concentration, Γ, to the bulk concentration, C, for which the governing transport equation is as

$$\frac{\partial C}{\partial t} + \boldsymbol{u} \bullet \nabla C = D_B \nabla^2 C \tag{36}$$

where D_B refers to the bulk diffusion coefficient. Further, for thin film flows on a flat substrate, the variation of liquid thickness is determined from the following equation:

$$\frac{\partial h}{\partial t} - \nabla \bullet \left(\frac{h^3}{3\mu} \nabla p - \frac{h^2}{2\mu} \nabla \gamma_{lv} \right) = 0\,. \tag{37}$$

Equations (35), (36) and (37) can be combined together to depict the dependence of the surface tension on the surfactant concentration and the surface velocity, $\boldsymbol{u}_s = (h\nabla\gamma_{lv}/\mu) - h^2\nabla p/(2\mu)$.

Capillary Spreading

Another variant of the surface tension driven flow that is of potential interest to the microfluidics research community is the capillary spreading phenomenon. Of particular interest can be the spreading of liquids on rough homogeneous substrates or on heterogeneous substrates with hydrophobic and hydrophilic stripes. For smooth homogeneous substrates, the radial advancement of a liquid of volume $\forall$ has been observed by Tanner [4] as

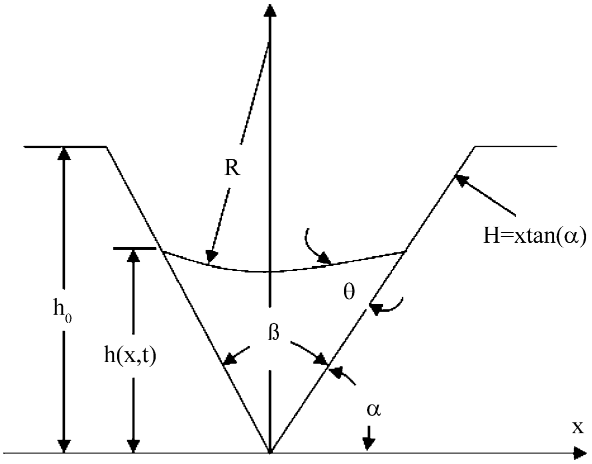
$$r(t) \sim \left(\frac{\gamma}{\mu} \forall^3 t \right)^{\frac{1}{10}} \tag{38}$$

which shows a rather weak dependence on time. However, careful analysis has revealed that a thin precursor film advances at a rate proportional to $\sqrt{t}$, following standard diffusion dynamics.
To illustrate the flow behaviour during capillary spreading in non-smooth surfaces, one may refer to the classical example of liquid spreading in V-shaped microgrooves (see Fig. 2 for the geometrical features of the cross section of the groove). For low Capillary number, the pressure drop across the groove is given by

$$\Delta p = p(x) - p(0) = -\frac{\gamma}{R(x)} \tag{39}$$

where $1/R(x) = \sin(\alpha - \theta)\tan\alpha / h(x,t)$. Following a quasi one-dimensional analysis, the flow rate can be obtained as [5]

$$Q = -\frac{h^4(x,t)}{\mu}\Gamma(\theta,\alpha)\frac{\partial p}{\partial x} \tag{40}$$



Surface Tension Driven Flow, Figure 2 Geometrical features pertinent to the liquid spreading in a V-microgroove

where

$$\Gamma(\theta,\alpha) \approx \Gamma(\alpha,\alpha) \left[\frac{h_c(\theta,\alpha)}{h_0} \right]^3 \left[\frac{\widehat{A}(\theta,\alpha)}{\cot\alpha} \right]^{\frac{1}{2}}\,. \tag{40a}$$

In Eq. (40a), h_c is the height of the fluid at the middle of the groove, and is given by

$$h_c(\theta,\alpha) = h_0 \left[1 + \cot\alpha \frac{\cos(\alpha-\theta) - 1}{\sin(\alpha-\theta)} \right]\,. \tag{40b}$$

The parameter $\Gamma(\alpha,\alpha)$ can be analytically approximated as

$$\Gamma(\alpha,\alpha) \approx \frac{1}{6} \frac{\cot^3\alpha + 3.4\cot^4\alpha + \cot^5\alpha}{1 + 3.4\cot\alpha + 4\cot^2\alpha + 3.4\cot^3\alpha + \cot^4\alpha}\,. \tag{40c}$$

Also, the function $\widehat{A}(\theta,\alpha)$ in Eq. (40a) is related to the cross sectional area $A(x,t)$ of the liquid inside the groove, as

$$A(x,t) = h^2(x,t)\widehat{A}(\theta(x,t),\alpha) \tag{40d}$$

where

$$\widehat{A}(\theta,\alpha) = \frac{\sin^2(\alpha-\theta)\tan\alpha - (\alpha-\theta) + \sin(\alpha-\theta)\cos(\alpha-\theta)}{\tan^2\alpha\sin^2(\alpha-\theta)}\,. \tag{40e}$$

S

The evolution of the height of the liquid inside the groove is derived from the continuity and the momentum conservation equation as

$$\frac{\partial h^2(x,t)}{\partial t} = \frac{D}{h_0}\frac{\partial}{\partial x}\left[h^2(x,t)\frac{\partial h(x,t)}{\partial x}\right] \tag{41}$$

where D is the diffusion coefficient, given by

$$D = \frac{\gamma h_0}{\mu\kappa(\theta_0,\alpha)} \,. \tag{41a}$$

In Eq. (41a)

$$\kappa(\theta_0,\alpha) = \frac{\Gamma(\theta_0,\alpha)\sin(\alpha-\theta_0)\tan\alpha}{(\theta_0,\alpha)} \,. \tag{41b}$$

It is interesting to note here that the value of D is positive if $\alpha > \theta_0$, which is equivalent to having a concave free surface. For $\alpha < \theta_0$, on the other hand, no capillary wicking takes place. Equation (41) has been solved in the literature [5] under various conditions. In the simple case of $h(0,t) = h_0$, a similarity solution can be attempted with $h(x,t) = h_0\phi(\eta)$, where $\eta = x/\sqrt{Dt}$. An approximate solution, in that case, can be obtained as

$$\phi(\eta) = -\frac{1}{2}\eta_0(\eta-\eta_0) - \frac{1}{2}(\eta-\eta_0)^2 - \frac{1}{108\eta_0}(\eta-\eta_0)^3 + \ldots \tag{42}$$

where η_0 is the location where the solution goes to zero and stays at zero. A major physical consequence of the above analysis is that the diffusion dynamics dominate for the capillary filling of microgrooves, and the leading edge (spreading front) propagates as

$$x_0(t) = \eta_0(\theta_0,\alpha)\sqrt{Dt} \,. \tag{43}$$

Thus, spreading increases with the depth of the groove, since $D \propto h_0$. The similarity solution also implies that free surface of the liquid spreading remains self-similar downstream.

By following an approach analogous to the above, Darhuber et al. [6] studied the dynamics of capillary spreading along hydrophobic microstripes. The smooth surface was processed chemically to create narrow hydrophilic stripes on a hydrophobic background. The equation governing the self-similar solutions, in that case, can be described as

$$\frac{\mathrm{d}}{\mathrm{d}\eta}\left(\phi^3\frac{\mathrm{d}\phi}{\mathrm{d}\eta}\right) + \frac{\eta}{2}\frac{\mathrm{d}\phi}{\mathrm{d}\eta} = 0 \tag{44}$$

where the similarity variables are defined similarly as before. An approximate solution in this case is given by

$$\phi(\eta) \approx \left(1 - \frac{\eta}{\eta_0}\right)^{\frac{1}{3}} \tag{45}$$

where $\eta_0 \approx 0.87$. Thus, the spreading front advances as $x(t) \propto \sqrt{Dt}$, where $D = 64\gamma h_0^3/35\mu w^2$, w being the width of the microstripe. The average streamwise speed, $\bar{u}$, scales as $\bar{u} \sim \gamma w^4/\mu x$.

Surface Tension Driven Flow in Microchannels

Surface tension driven flows not only take place in open conduits such as microgrooves, but are also quite common in capillary tubes and microchannels. In a generic form, one can write the equation of motion describing the capillary advancement as

$$\frac{\mathrm{d}}{\mathrm{d}t}(MV_\mathrm{c}) = \sum F \tag{46}$$

where M is the fluid mass being transported, V_c is the velocity of its centre of mass and $\sum F = F_\text{surface tension} + F_\text{viscous} + F_\text{gravity}$. To illustrate the use of the above equation in simple forms, one may consider the viscous, incompressible and Newtonian flow against the direction of gravity along a long cylindrical capillary of radius r. For this case, one may first assume that $M = \rho\pi r^2 z$, $V_\mathrm{c} = \dot{z}$, $F_\text{surface tension} = 2\pi r\gamma\cos\theta$, $F_\text{viscous} = -8\pi\mu z\dot{z}$(assuming fully developed flow) and $F_\text{gravity} = -\rho g z$, where z is axial displacement of the capillary front. This leads to the following equation of capillary motion

$$\rho[z\ddot{z} + \dot{z}^2] = \frac{2}{r}\gamma\cos\theta - \frac{8}{r^2}\mu z\dot{z} - \rho g z \,. \tag{47}$$

Equation (47) suffers from a fundamental drawback that as $t \to 0$, $M \to 0$ (since $z \to 0$), giving rise to an ill-posed problem with infinite initial acceleration. This ambiguity can be physically resolved by referring to the equation of continuity, based on which it can be inferred that in the onset of the capillary rise, the liquid present in the dipped portion of the capillary and the bulk reservoir to which it is connected also starts moving at the same time. This additional mass of fluid inducted into the motion initially is known as the added mass, m_0. This added mass can be approximated by executing a potential flow analysis for an incoming spherical liquid element of radius r that moves with a velocity $\dot{z}$. Executing this analysis, one can obtain, for a cylindrical tube [7],

$$m_0 \approx \frac{3\rho\pi r^3}{8} \,. \tag{48}$$

The above is equivalent to the introduction of an additional term in the left hand side of Eq. (56), in the form $3\rho r\ddot{z}/8$, which eliminates the prediction of an unrealistic initial burst as $t \to 0^+$.

Equation (47), with the modifications introduced by Eq. (48) physically represents a rather simplified situation. In reality, a number of other complicating factors may be present, resulting in further modifications in the equation of capillary advancement. For example, the capillary walls can adsorb surfactants from the bulk solution, leading to a continuous variation in the surface tension coefficient. The adsorption of the surfactant, Γ_{lv}, can lead to an axial gradient of surface tension, following the Gibbs equation:

$$\gamma = \gamma_0 - \bar{R}T \int_{C=0}^{C(z,t)} \Gamma_{\mathrm{lv}} d \ln C \tag{49}$$

where C is the surface concentration of the surfactant. Phenomenologically, one may carry out an approximate analysis by posing an exponentially decaying time-dependence of the second term appearing in Eq. (49), such that

$$\gamma = \gamma_0 - \Delta\gamma\phi_{\mathrm{B}}(t) \tag{50}$$

where

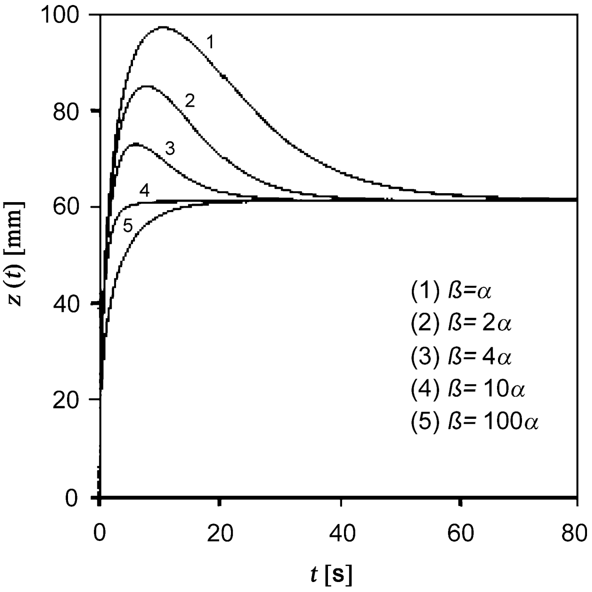
$$\Delta\gamma = \gamma_0 - \gamma_\infty\,, \quad \phi_{\mathrm{B}}(t) = 1 - \exp(-\beta t)\,. \tag{50a}$$

Here γ_0 is the initial surface tension, γ_∞ is the equilibrium surface tension and β is a relaxation constant. This effect can be introduced in Eq. (47) by first differentiating the same with respect to time, neglecting the terms containing the products $\dot{z}\ddot{z}$ and $z\dddot{z}$ in the quasi-steady limit, to set

$$-\frac{2\beta\Delta\gamma\cos\theta}{r}\exp(-\beta t) = \frac{8\mu}{r^2}[\dot{z}^2 + z\ddot{z}] + \rho g\dot{z}\,. \tag{51}$$

Typical numerical solutions of Eq. (51), following Zhumud et al. [8], are presented in Fig. 3. A maximum occurs in the characteristic displacement curves only when the surface tension relaxation is not as fast as compared to the capillary filling. More simplistic scaling estimates in the capillary rise phenomenon can readily be obtained by noting that within certain limits, the capillary rise represents a quasi-steady process, in which the amount of surfactant adsorbed to the solid/liquid interface per unit time is equal to that transported to the liquid/vapour interface by diffusion, which implies

$$2\pi r\Gamma_{\mathrm{sl}}^m dz \sim \pi r^2 D\frac{C_{\mathrm{b}}}{\sqrt{Dt}}\,\mathrm{d}t \tag{52}$$



Surface Tension Driven Flow, Figure 3 Simulated capillary rise dynamics for aqueous solutions of surfactants. In the figure, $\alpha = \rho g r^2/8\eta z_{t\to\infty}$. For obtaining the plots, following data are taken: $r = 10^{-4}$ m, $\eta = 10^{-3}$ Pa, $\rho = 10^3$ kg/m^3, $\theta = 0$, $\alpha = 8.3 \times 10^{-2}$ s^{-1}

where Γ_{sl}^m is the adsorption capacity of the monolayer per unit area and C_{b} is the bulk concentration of the surfactant. From Eq. (52), one can obtain

$$z(t) \sim \frac{rC_{\mathrm{b}}}{\Gamma_{\mathrm{sl}}^m}\sqrt{Dt} \tag{53}$$

which physically implies the condition of a diffusion-limited capillary advancement.

The real physical picture of surface tension driven capillary motion appears to be much more complicated than what is depicted by Eq. (47). First of all, the viscous resistance terms need to be modeled more carefully. In reality, as the fluid enters the microchannel, the flow passes through a short entrance region, followed by a fully developed region. A third region, namely the meniscus traction region, also comes into play, because of the influence of the free surface of the meniscus on the flow. This can alter the velocity profiles significantly, and the predicted drag force can appear to be significantly different from that obtained from the considerations of a fully developed Poiseullean velocity profile. These effects have recently been taken into account for analyzing the surfacetension driven flow of blood in microfluidic channels. Details of the underlying physical principles to model the modified viscous drag are presented in the article on ► capillary filling, and are not repeated here for the sake of brevity. Another interesting and important consideration is

S

the modeling of the dynamic evolution of an apparent contact angle, which can effectively represent a gross manifestation of the sub-continuum picture close to the interfaces that cannot be directly resolved in the system-level calculations. It needs to be noted in this context that the capillarity effect within the microchannel essentially implies that a fluid–fluid interface and the fluid–solid interface intersect to form a common line of contact, or a tri-junction. In order to model such moving contact lines appropriately, one needs to first qualitatively assess the physical phenomena influencing the capillarity. In this regard, it has been experimentally shown that points on the interfacial lines arrive at the contact line within a finite time span. Therefore, one must pose an effective slip law that relieves a force singularity condition by ensuring that a finite force is necessary to move the contact lines of a fluid, irrespective of the no-slip boundary conditions classically being applied at the channel walls. In order to mathematically ensure this effect, one needs to pose a condition on the contact angle θ, as a function of velocity of the contact line. In a physical sense, this departure of contact angle from its static equilibrium value is mainly due to viscous bending of the interface near the contact lines. Although exact mathematical quantification of the dynamic evolution of this contact angle may be somewhat involved, experimental studies have revealed that the apparent dynamic contact angle, θ_a, that the liquid forms with the solid surface is closely described by a universal scaling relationship at low speeds, known sometimes as Tanner's law, which can be mathematically stated as

$$\theta_a \sim \mathrm{Ca}^{\frac{1}{3}} \tag{54}$$

where $\mathrm{Ca} = \mu u/\gamma$ is the capillary number, and u is velocity of the contact line. However, in order to quantify the proportionality constant, one must resolve the asymptotic behavior of the thin liquid film in vicinity of the microchannel wall. This thin film region can further be divided into two parts, namely, (a) a lubricating film region followed by (b) a precursor film region as one moves along the direction of wetting. In the precursor film region, one expects the interfacial length scales to approach molecular scales, as intermolecular forces become important. Behind the lubricating film, on the other hand, the length scales are quite large (of the order of r), and a potential challenge remains in devising a quantitative expression for dynamic evolution of θ_a by asymptotic matching from solutions to these regions of widely different length scales. For analysis of the same, one may assume negligible gravitational effects (typically characterized by a low Bond number, $\mathrm{Bo} = \rho g r^2/\gamma$), and viscosity of the gas phase negligible in comparison to that of the liquid phase so that dynamics of the two phases are essentially decoupled. In that situation, the domain of interest can be divided into two regions, namely

- the outer region where the lateral and vertical length scales are both O(1) and
- the inner lubrication region in which the lateral and vertical length scales are $O(\mathrm{Ca}^{\frac{1}{3}})$ and $O(\mathrm{Ca}^{\frac{2}{3}})$, respectively, as capillary and viscous forces balance.

Further division of the inner region may be necessary when the intermolecular forces become important at very thin films. In the lubricating film region, this effect can be incorporated by invoking an extra term of the same dimension as that of pressure in the overall force balance, which can be described as $A/6\pi z^3$, z being the film thickness. This term is known as the ▶disjoining pressure. The parameter A is called the Hamaker's constant (for a further detailing, see the next sub-section), which is negative for wetting fluids. It is important to note here that one needs to be extremely careful in introducing intermolecular forces into a continuum model such as the Navier–Stokes equation. In particular, the surface tension force, which is due to intermolecular forces between the gas and liquid phases, cannot be considered separately from the Van der Waals forces between the gas and the solid phases for very thin films. If one introduces a molecular length scale R_m as $R_m = (|A|/6\pi\gamma)^{\frac{1}{2}}$, or its dimensionless counterpart $\lambda = R_m/r$; the above-mentioned model for lubricating film is valid if its film thickness is much larger than R_m, i. e., $\mathrm{Ca}^{\frac{2}{3}} \gg \lambda$. Since R_m is typically of the order of a few Angstroms, while a typically capillary radius is of the order of 10^{-1} mm, the lower bound on Ca is of the order of 10^{-4}. Beyond this lower bound, the continuum model remains valid for the lubricating film. At relatively larger Ca, the intermolecular forces would turn out to be less effective, so that dependence of Tanner's law on λ becomes progressively weaker. For a significantly large Ca, the meniscus speed may exceed the wetting speed and the meniscus may reverse its curvature as the contact angle passes through 90° . However, the foregoing analysis assumes that such situations do not occur, and accordingly, it remains valid for $\theta < 90°$. An asymptotic matching may accordingly be done between the outer region and the precursor film through the lubricating film at the inner region. At the front of this region, however, intermolecular forces and a vanishingly small film (spread by fast wetting) stipulate a hyperbolic decay of the film thickness towards zero. Accordingly, a universal relationship for dynamic evolution of the contact angle can be obtained as [9]

$$|\tan\theta_a| = 7.48\mathrm{Ca}^{1/3} - 3.28\lambda^{0.04}\mathrm{Ca}^{0.293} \tag{55}$$

It can be noted here that λ is typically of the order of 10^{-8} for wetting fluids flowing through a microcapillary channel having hydraulic radius of the order of 1 mm. Physically, for very low values of Ca, the corresponding correction term appearing in Eq. (55) may become important, where intermolecular forces come significantly into play and $\tan\theta_a$ diverges slightly away from the asymptotic behavior characterized by Eq. (54) towards lower values. Mathematically, Eq. (55) has been derived from a matched asymptotic analysis that matches a static outer region to the precursor adhering the wall, through an intermediate lubricating film. The problem, hence, is characterized by three length scales, namely, the capillary radius, film thickness and molecular length scale (λ). This interconnection is captured by Eq. (55), and the outcome is very much analogous to the slip model obtained by Hoffman [10], which gives the variation of θ_a as a function of slip length as:

$$g(\theta_a) = g(\theta_a(0)) + \mathrm{Ca}\ln\left(\frac{k}{l_s}\right) \tag{56}$$

where the slip length scale is given by: $l_s \sim l_d/\mathrm{Ca}$, l_d being of the order of wall roughness and k being a slip-model dependent constant. Exact for of $g(\theta_a)$ is available in Hoffman [10], which is as

$$g(\theta_a) = \int_0^\theta d\phi\,[f(\phi)]^{-1} \tag{57}$$

where

$$f(\phi) = \frac{2\sin\phi(A+B+C)}{D+E} \tag{57a}$$

where

$$A = q^2\left(\phi^2 - \sin^2\phi\right),$$

$$B = 2q\left[\phi(\pi-\phi) + \sin^2\phi\right],$$

$$C = (\pi-\phi)^2 - \sin^2\phi,$$

$$D = q\left(\phi^2 - \sin^2\phi\right)[(\pi-\phi) + \sin\phi\cos\phi],$$

$$E = (\phi - \sin\phi\cos\phi)\left[(\pi-\phi)^2 - \sin^2\phi\right].$$

In Eq. (57a), q is the ratio of viscosity of the liquid and the vapour. Typical values of the factor k, as reported in the literature [10], can be of the order of 10^{-1} to 10.

Molecular Level Modeling of Wetting Phenomena

The mathematical descriptions outlined in most of our preceding discussions represents a continuum-based picture of the wetting phenomenon and the consequent surface tension driven flow. However, from a more fundamental perspective, these are strongly influenced by the underlying molecular picture; more precisely, through the intermolecular interaction potentials (adhesion and cohesion). One may quantify the net effect of the interaction potentials on the wetting behaviour by considering a liquid film of thickness l on a solid substrate. For strong solid–liquid adhesive interactions, the system can lower its free energy by increasing the distance between the solid–liquid and the liquid–vapour interfaces. This leads to a net repulsion force per unit area between the solid–liquid and the liquid–vapour interfaces, which is called the disjoing pressure, $\Pi(l)$. The disjoing pressure can be related to the effective interface potential, $V(l)$ as per the following relationship:

$$\Pi(l) = -\frac{\mathrm{d}V(l)}{\mathrm{d}l}. \tag{58}$$

The excess free energy of the liquid film, accordingly, can be estimated as

$$E_s(l) = \gamma_{lv} + \gamma_{sl} + V(l). \tag{59}$$

A fundamental estimate of the excess free energy of the liquid film can be provided by the density functional theory, which is based directly on the microscopically specified molecular interactions. In its simplest form, the free energy functional, E_s, can be represented as [11]

$$\begin{aligned} E_S = {} & \underbrace{E_{hc}\left(\{\rho(\mathbf{r})\}, T\right)}_{\text{hard core interactions}} \\ & + \frac{1}{2}\int \underbrace{d^3r d^3r' \tilde{w}\left(|\mathbf{r}-\mathbf{r}'|\right)\left(\rho(\mathbf{r})\rho(\mathbf{r}') - \rho_b^2\right)}_{\text{long range particle-particle interactions}} \\ & + \int \underbrace{d^3r U(\mathbf{r})\rho(\mathbf{r})}_{\text{particle-wall interactions}} \end{aligned} \tag{60}$$

where $\tilde{w}\left(|\mathbf{r}-\mathbf{r}'|\right)$ is the long-ranged part of the particle-particle interaction potential in the liquid phase, ρ_b is the particle-density far from the wall, and $U(\mathbf{r})$ is the interaction potential of a fluid particle with the wall particles. The density profile, $\rho(\mathbf{r})$ can be found by minimizing Eq. (60). Despite being quite straight forward in principle, a execution of this task, however, is rather difficult, owing to the slow decay of parts of the interaction potential. Because of such practical constraints, quantitative predictions based

S

on numerical solutions of the full density functional theory has been rather limited, except for wetting behaviour of simple atoms or molecules (e. g. He) on simple substrates (e. g. Cs) at zero temperature [12]. However, for He, quantum effects also need to be taken into account while formulating the density functional, which takes the following form [12]:

$$E_S = \frac{\hbar^2}{2m} \int \underbrace{d^3 r \left\{ \nabla \left[\rho^{\frac{1}{2}} \right] (\mathbf{r}) \right\}^2}_{\text{quantum kinetic energy}} + \int \underbrace{d^3 r U(\mathbf{r}) \rho(\mathbf{r})}_{\text{particle-wall interactions}} + \underbrace{H_{NL}}_{\text{short range correlations in the liquid}} \tag{61}$$

where the non-local Hamiltonian, H_{NL}, is given by

$$H_{NL} = \frac{1}{2} \int d^3 r d^3 r' \rho(\mathbf{r}) \rho(\mathbf{r}') \tilde{w}(|\mathbf{r} - \mathbf{r}'|) + \frac{c}{2} \int d^3 r \rho(\mathbf{r}) [\bar{\rho}(\mathbf{r})]^{1+\gamma} . \tag{61a}$$

Phenomenologically, H_{NL} accounts for short-range interactions and correlations between the He atoms, and involves a spatially-averaged density, $\bar{\rho}$. One major limitation of expression (61), however, is that it is restricted to $T = 0$, so that it cannot predict the wetting temperature. For wetting of quantum liquids, an alternative approach was introduced by Cheng et al. [12]. As per this consideration, under the assumptions of a sharp interface bounding the wetting layer, the surface free energy of the substrate can be approximated as

$$\gamma_{sl} = \gamma_{sv} + \tilde{\gamma}_{sl} + \rho_b \int_{z_{min}}^{\infty} U(z) dz \tag{62}$$

where $\tilde{\gamma}_{sl}$ is the cost of making the liquid density vanish at the substrate, and is taken to be equal to γ_{lv}. This simple model also assumes the liquid density in the film to be same as the bulk liquid density. The potential is taken as follows:

$$U(z) = \frac{4C_3^3}{27D^2 z^9} - \frac{C_3}{z^3} \tag{63}$$

where C_3 gives the amplitude of the van der Waals interaction between one particle and the substrate, and D is the well-depth of the substrate-adsorbate interaction potential. In addition, if z_{min} is taken to be the minimum of $V(l)$, the wetting transition temperature can be calculated by solving

$$\left(C_3 D^2 \right)^{\frac{1}{3}} = \frac{3.33\gamma(T)}{\rho_l - \rho_v} . \tag{64}$$

It is important to note here that for wetting phenomena, an important contribution to the disjoining pressure arises from the van der Waals interaction ($w(r) \propto 1/r^6$), which includes dipole-dipole, dipole-induced dipole and induced dipole-induced dipole interactions. Performing a volume integral over all the molecules present in the two half-spaces bounding the film, one finds a decay of the form $\Pi(l) \approx A/(6\pi l^3)$, where A is known as the Hamaker constant, which physically gives the amplitude of the interaction. Fundamentally, the Hamaker constant can be calculated in terms of the dielectric properties of the three phases. For example, one can employ a simple approximation by first considering the contribution due to dipolar interactions, given by the zero-frequency permittivities of the respective phases, as [13]

$$A_{\nu=0} = -\frac{3}{4} k_B T \frac{(\varepsilon_1 - \varepsilon_3)(\varepsilon_2 - \varepsilon_3)}{(\varepsilon_1 + \varepsilon_3)(\varepsilon_2 + \varepsilon_3)} \tag{65}$$

where 1(solid) and 2(vapour) denote the phases in the two half-spaces and 3(liquid) is the intermediate phase. For non-zero frequencies, on the other hand, the contribution comes from the relative refractive indices of the three phases, as

$$A_{\nu>0} = -\frac{3h\nu_{UV}}{16\sqrt{2\left(n_1^2 + n_3^2\right)\left(n_2^2 + n_3^2\right)}} \frac{\left(n_1^2 - n_3^3\right)\left(n_2^2 + n_3^2\right)}{\sqrt{\left(n_1^2 + n_3^2\right)} + \sqrt{\left(n_2^2 + n_3^2\right)}} \tag{66}$$

where h is the Planck's constant and ν_{UV} ($\approx 2 \times 10^6$ Hz) is the UV frequency for which the relative refractive indices of the phases become identical (close to unity). In practice, the Hamaker constant is the sum of the two contributions given by Eqs. (65) and (66). Equaion (65) retains the $1/l^2$ dependence for all distances. However, Eq. (66) is subject to retardations, since interactions between dipoles travel only at the speed of light. It also follows from Eq. (66) that for two identical phases1 and 2 separated by a dissimilar phase 3, the net effect is an attractive van der Waals interaction ($A < 0$) between the two interfaces. In typical situations involving surface tension driven flows, the nature of

the contribution given by Eq. (66) is dominated by the relative refractive index difference between the liquid and the solid, since the refractive index of the vapour would generally be close to unity. If the liquid has a refractive index between that of the solid and the vapour, then $A > 0$ and the formation of the wetting layer is preferred (because of an effective repulsion between the interfaces).

A close inter-connection between the molecular and the continuum theories of surface tension driven phenomena can be provided by the equilibrium spreading coefficient, $S = \gamma_{sv} - \gamma_{sl} - \gamma_{lv}$, which physically represents the surface free energy difference between partial and complete wetting. When S is negative, it becomes unfavourable to replace the solid-vapour interface by two others, as pertinent to the partial wetting state. The phenomenological theory of Cahn [14] gives an explicit way to calculate the value of S, from molecular considerations. As per this theory, the surface free energy functional is given as

$$E_s = \underbrace{\phi(\rho_s)}_{\text{wall interaction}} + \int_0^{\infty} \underbrace{\left[\omega(\rho) + c^2/4\left(\frac{d\rho(z)}{dz}\right)^2\right] dz}_{\text{liquid–vapour interaction}} \tag{67}$$

where ω is the grand potential per unit volume, $\rho(z)$ is the density profile as a function of the distance z from the solid surface and $\rho_s = \rho(0)$ is the value of density at the substrate. In principle, Eq. (67) intends to represent a similar physical behaviour as that depicted by Eq. (60), except for the fact that long-ranged interactions are not included in Eq. (67). The wall-interaction term in Eq. (67) is usually expanded to the second order, as

$$\phi(\rho_s) = -h_1\rho_s - g\rho_s^2/2 \tag{67a}$$

where the parameters h_1 and g are referred to as the short-range surface field and the surface enhancement field, respectively. The parameter h_1 describes the preference of the substrate for either the liquid or the vapour, and can be taken proportional to the difference between the substrate–liquid and substrate–vapour interfacial tensions. If $h_1 > 0$, the liquid is preferred at the wall, whereas for $h_1 < 0$, the vapour is preferred. The parameter g (usually a small negative number) is a measure of the 'missing' liquid–liquid interactions due to the fact that a liquid molecule near the wall has a small number of liquid neighbours than the bulk. The grand potential in Eq. (67) can be estimated by employing the classical Landau expansion around the critical point (in units of $k_B T$), in the form of

$$\omega = a_2\rho^2 + a_4\rho^4 \,. \tag{67b}$$

Based on this, the spreading coefficient, S, can be calculated explicitly, as

$$S = c\rho_0/12\left(\left[\kappa^2 + 4(1+\chi)\right]^{\frac{3}{2}} - \left[\kappa^2 + 4(1-\chi)\right]^{\frac{3}{2}}\right) + 3\chi\kappa/4 - 4c\rho_0^3/3 \tag{68}$$

where $\pm\rho_0$ are the bulk densities, $\chi = h_1/c\rho_0^2$ and $\kappa = g/c\rho_0$.

Key Research Findings

Numerous applications of surface tension driven microflows have been presented in the recent literature. Jun and Kim [15] demonstrated the pumping of fluids in microchannels using the movement of a single or multiple vapor bubbles The pumping mechanism required no micromechanical moving components for actuation, and essentially operated by utilizing an asymmetric heating that creates a variation in vapor pressure and surface tension due to the heater-induced temperature gradient along the channel. A heat and mass transfer analysis was performed to model the pumping mechanism and to estimate the pumping capability of the device. Experimental results were also presented to establish the proposition. Chakraborty and Som [16] theoretically determined the rate of heat transfer in a thin evaporating liquid film flowing along the walls of a microchannel under the combined action of surface tension and gravity. Analytical solutions of conservation equations, in both liquid and vapour phases, were obtained in their study. Lee and Kim [17] demonstrated the first microelectromechanical systems (MEMS) device that adopts surface tension as the driving force, by driving a liquid-metal droplet in an electrolyte-filled capillary, by locally modifying the surface tension with electric potential. Certain key issues in practical implementation were identified and investigated, including the problems of material compatibility, electrode polarization, and electrolysis, as well as the micromachining process. Based on these understandings, they demonstrated a liquid micromotor in the form of an electrolyte and liquid-metal droplets rotating along a microchannel loop. Smooth and wear-free rotation of the liquid system was shown at a speed of approximately 40 mm/s, with a driving voltage of only 2.8 V and a little power consumption (10 – 100 W). Chakraborty [18] investigated the breakup of viscous liquid droplets on surface tension modulation during micro-welding metal transfer. This study was motivated by the fact that viscous jets of a molten metal ready to be transferred into the arc welding pools are inherently unstable. From this study, a variation of the time required for droplet formation was obtained as

a function of the surface tension modulation, corresponding to different instability modes. Chan and Yang [19] presented theoretical and experimental studies of the surface-tension-driven, two-immiscible liquid–liquid displacement in a horizontal capillary. A one-dimensional mathematical model was developed to describe the capillary displacement of a fixed liquid column by another liquid that continuously flows into the capillary by surface tension. Experiments for a water column displaced by silicon oil were carried out to examine the underling dynamics in practice. It was found that a faster and longer displacement was achieved for a shorter water column in a larger capillary. Their theoretical predictions agreed well with the experimental results. In a recent study, Chakraborty [20] devised a novel mathematical approach to analyze the surface tension driven flow of blood from a droplet into a microcapillary channel. Special attention was devoted to estimate the effects of variable hydraulic resistance over different flow regimes, influence of suspended RBC particulates on the non-Newtonian flow characteristics and implications of a dynamically-evolving contact angle. These studies have subsequently been extended for capillary transport in presence of electroosmotic effects [21]. There have also been other recent applications on modeling of surface tension driven microflows (for details, please refer to the articles on ► electrocapillary, ► capillary filling and ► droplet dynamics in microchannels), elucidating comprehensive applications of the underlying theory.

Future Directions For Research

Future research in the modeling of surface tension driven flows can be directed towards the development of integrated multi-scale models that can more effectively represent the sub-continuum (essentially, molecular level) level transport features in the framework of continuum based descriptions of the surface tension aided microfluidic transport.

Definition

Taylor flow is a type of gas–liquid flow pattern that consists of elongated bubbles with equivalent diameter usually many times that of the channel diameter, separated by liquid slugs (Fig. 1). The bubbles adopt a characteristic capsular shape and can either completely or nearly completely fill the channel cross-section where at most a thin liquid film separates them from the channel wall.

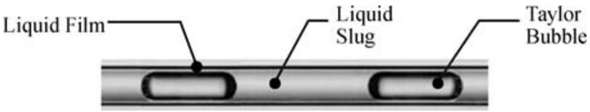
Chemical and Physical Principles

Definition of Small Channels

Taylor flow is a dominant pattern during gas–liquid flow in small channels. Channels are generally considered to be small when the surface tension forces dominate the gravitational forces. A measure of the relative importance of the two forces is given by the Bond or Eötvös number (both names are invariably used in the literature)

$$\text{Bo or Eö} = \frac{(\rho_g - \rho) g d^2}{\gamma} \tag{1}$$

where ρ_g and ρ are the gas and liquid densities, respectively, g is the gravitational acceleration, d is the tube diameter and γ is the surface tension. Investigators have suggested different values of the Bo or Eö number below which channels can be considered small, ranging from 0.88 to $(2\pi)^2$. Bretherton [1] has observed that a Taylor bubble no longer rises spontaneously in a water-filled capillary under the effect of gravity for Bo < 3.37 and this value can also be used to define small channels.



Taylor Flow in Microchannels, Figure 1 Gas–liquid Taylor flow

Flow Patterns

In small channels a number of flow patterns can be observed and the same terminology and classifications as in large channels are commonly used. Because of the dominance of the surface tension forces stratified flow is rarely observed in small channels. In general, bubble flow appears at low gas flowrates. As the gas flowrate increases Taylor bubbles form. With further increase in the gas flowrate annular flow appears with the liquid forming an annulus which wets the wall. At high gas and liquid flowrates, churn flow occurs where there is a liquid film at the wall and the gas flow in the center is interrupted by the frequent appearance of frothy bubbles and slugs.

As the dimensions of the channel reduce, Taylor and annular flows dominate, while patterns specific to small channels appear (such as ring, liquid lump, Yakitori and rivulet flows). These can be considered to be variations of the Taylor and annular regimes. For a review of gas–liquid flow patterns in microchannels see Ghiaasiaan and Abdel-Khalik [2].

Key Research Findings

Flow Patterns in Liquid Slugs

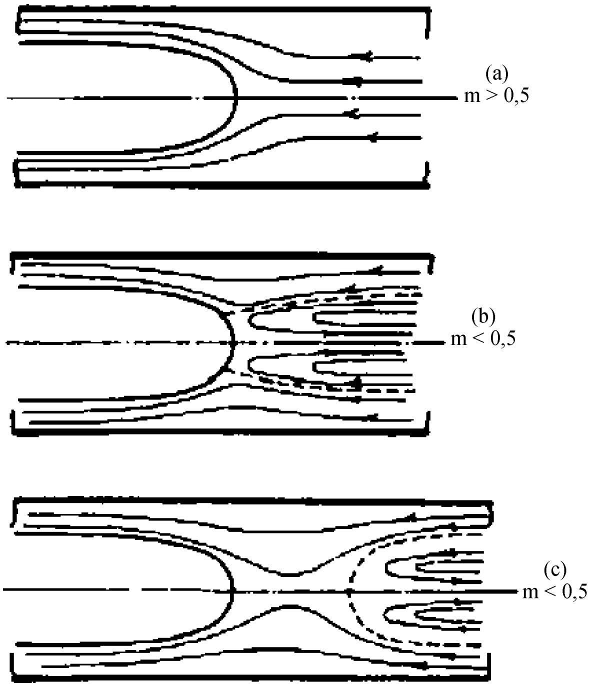
Qualitative sketches of the flow streamlines in the liquid slug ahead of the bubble have been presented by Taylor [3] (see Fig. 2). These were related to the Capillary number, Ca ($Ca = \mu U_b/\gamma$, where μ is the liquid viscosity and U_b is the bubble velocity) and to the dimensionless number m, that gives the relative velocity between the bubble and the liquid

$$m = \frac{U_b - U_{ls}}{U_b} \tag{2}$$

where U_{ls} is the average liquid slug velocity. At high values of Ca, for $m > 0.5$, complete bypass flow was suggested with a single stagnation point at the bubble front. At low values of Ca, for $m < 0.5$ two possible reversal flow patterns were envisaged, one featuring a stagnation ring around the bubble cap (Fig. 2b) and the other featuring a single stagnation point at the bubble cap tip and a second one inside the liquid slug (Fig. 2c).

Although patterns 2a and 2b have been confirmed experimentally and theoretically by many investigators, pattern 2c was observed for the first time in numerical studies [4]. For no inertia and high Ca, a single stagnation point on the bubble tip was seen. As Ca decreased, there was a transition and vortices started to appear at $Ca = 0.69$, as suggested by pattern 2c. A stagnation ring finally developed at $Ca = 0.60$ (pattern 2b). The small range of Ca values, $0.60 < Ca < 0.69$, within which pattern 2c appeared would explain why it had not been observed experimentally before. At the back of the bubble, it was found [5] that as Ca increases from 0.60 to 0.69 the vortex breaks into two regions, a swirl and a recirculating flow separated by a stagnation point, whose sizes diminish as Ca increases.

The analytical model developed by Thulasidas et al. [6], which is suitable for bubble train flow, showed that the transition to complete bypass (pattern 2a) occurs in horizontal flow at $Ca = 0.7$, in upward flow at $Ca = 0.5$ and in downward flow at $Ca = 0.6$.



Taylor Flow in Microchannels, Figure 2 Streamlines in the liquid slug in front of the Taylor bubble [3]

Film Thickness and Bubble Shape

The flow of a long bubble in a capillary is a classical problem in fluid mechanics. Bubbles have been used as tracers in capillaries filled with liquid in order to determine liquid velocity. This application led to the discovery that when a wetting viscous liquid is displaced by a gas bubble in a capillary a liquid film is deposited on the wall. Initial experimental findings that the thickness of the film was proportional to $Ca^{1/2}$ were confirmed and extended to $Ca = 10^{-1}$ [3]. In his pioneering approach, Bretherton [1] assumed creeping flow in the liquid and used lubrication theory for the region of the film between the end of the spherical bubble cap and the flat film behind it to calculate the thickness of the film, the pressure drop and

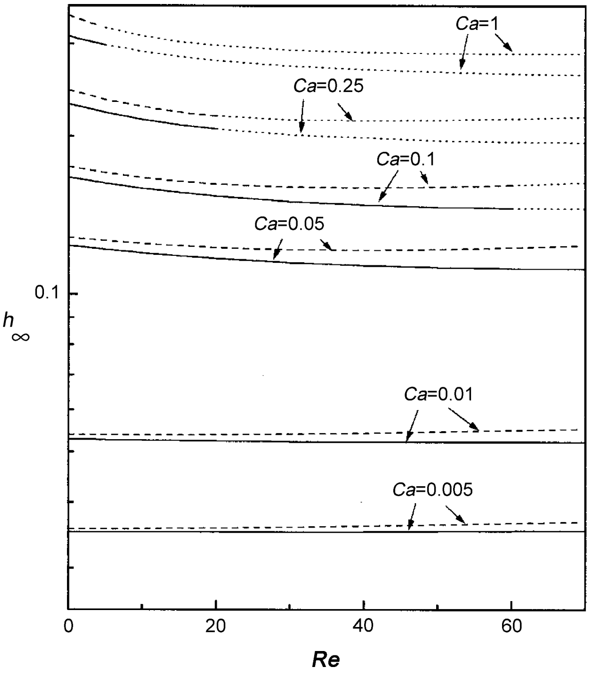
the shape of the bubble. The Taylor bubble was taken to be inviscid with spherical caps. From this analysis it was found that the thickness of the film can be obtained from $\delta/d = 0.66\,\mathrm{Ca}^{2/3}$. This finding should be valid for low values of Ca. Surprisingly, however, the experiments agreed better with the theory for $\mathrm{Ca} > 10^{-3}$, while at lower Ca, where the theory should hold exactly, the thickness of the film was substantially larger than the theoretical values. This discrepancy was later attributed to the presence of surface-active contaminants that are absorbed at the interface. Ratulowski and Chang [7] argued that surface contamination can be correctly assessed only if the surface tension is allowed to vary along the interface. A model was developed that included surfactant transportation at both the interface and in the bulk liquid and showed that an increase in the thickness of the film occurs if the surfactant transport in the bulk is mass transfer limited.

For higher values of Ca ($\mathrm{Ca} > 5 \times 10^{-3}$), numerical studies are required to obtain the shape of the bubble and the thickness of the film. A number of numerical solutions to the problem have been suggested, which also validate Bretherton's approach at very low values of Ca. As the front profile and the thickness of the film of a long Taylor bubble with sufficient separation between the bubbles can be approximated by that of an infinitely long bubble, many early studies, considered semi-infinite bubbles.

In later studies the effect of inertia at increased Reynolds numbers ($\mathrm{Re} = \rho U r/\mu$, where r is the channel radius) was considered. Giavedoni and Saita carried out extensive numerical simulations and analyzed the front [4] of a Taylor bubble for $10^{-5} < \mathrm{Ca} < 10$, $\mathrm{Re} < 70$, and the back [5] of a Taylor bubble for $10^{-3} < \mathrm{Ca} < 1.5$, $\mathrm{Re} < 70$. Because of the development of a constant film thickness it is possible to study the front and rear parts of the bubble independently. The influence of increasing Re on film thickness was found to be weakly non-monotonic where an initial decrease was followed by an increase (see Fig. 3). Later studies at even higher Re confirmed the trend of increasing thickness of the film as Re increased further. For $\mathrm{Ca} < 0.01$, however, inertial forces do not have an effect on film thickness.

Experimentally determined film thickness correlations have been listed by Edvinsson and Irandoust [8]. Based on scaling arguments in a semi-infinite bubble, a correlation was suggested [9] for the film thickness in the visco-capillary regime (where the thickness of the film depends only on Ca) that agreed well with Taylor's data and at very small Ca with Bretherton's model. After fitting it against experimental data the correlation became

$$\frac{\delta}{d} = \frac{0.66\,\mathrm{Ca}^{2/3}}{1 + 2.5\left(1.34\,\mathrm{Ca}^{2/3}\right)} \qquad (3)$$



Taylor Flow in Microchannels, Figure 3 Thickness of the film over the half-channel size (h_∞) against Reynolds number for plane flow (dashed lines) and axisymmetric flow (solid lines). Dotted lines represent situations that may not be feasible in practice [4]

At $\mathrm{Ca} > 10^{-3}$ inertial effects become important (visco-inertial regime) and the film thickness becomes larger than the one obtained by Eq. (3). Interestingly, this difference increases as the diameter of the tube increases. In the inertial regime [9]

$$\frac{\delta}{d} \propto \frac{\mathrm{Ca}^{2/3}}{\left(1 + \mathrm{Ca}^{2/3} - \mathrm{We}\right)} \qquad (4)$$

T

The Weber number, We, is defined as $\mathrm{We} = \rho U_b^2 (r-h)/\gamma$, where h is the thickness of the film deposited on the wall. The simulations by Giavedoni and Saita showed that the bubble front tended to adopt the shape of an arc of a circle for decreasing values of Ca. Undulations, which increased with Re, appeared at the back of the bubble. The size of the undulations depended on both Ca and Re and for $\mathrm{Ca} > 0.5$ no undulations were observed. For all the values of Re that were tested the rear of the meniscus was convex at first, became flat as Ca increased and then adopted a concave shape, while as Re increased the change from flat to concave shape appeared at lower values of Ca. The interface at the back of the bubble close to the meniscus tip is an almost perfect hemisphere for $\mathrm{Ca} < 10^{-3}$.

Thulasidas et al. [6] found experimentally that the thickness of the film was almost the same in horizontal and downward flows but was twice as much in upward flows.

Bubble Velocity

Because of the film between the bubble and the wall, the bubble and liquid velocities are not the same. The bubble velocity, U_b, is given by the drift flux model

$$U_\mathrm{b} = CU_\mathrm{ls} + U_0 \tag{5}$$

where C is an experimentally determined coefficient and U_0 is the bubble rise velocity in a stagnant liquid. For very small capillaries the bubble rise velocity is very small or zero (see also the definition of small channels given above). The bubble motion is often characterized by the dimensionless number m (see Eq. (2)). For low values of Ca, $m = 1.0\,\mathrm{Ca}^{1/2}$ which was found to be valid for $\mathrm{Ca} < 10^{-1}$ [3].

Bretherton's [1] analytical approach resulted in the following expression:

$$m = 1.29\,(3\,\mathrm{Ca})^{2/3} \tag{6}$$

Thulasidas et al. [6] compared their and all other available experimental data on relative bubble velocity, m, with the literature correlations. There was a considerable scattering of the experimental data at the lower values of Ca, particularly for $\mathrm{Ca} < 10^{-2}$, while Bretherton's correlation was found to underpredict all the data. The results showed that m reached a limiting value of 0.58 at large values of Ca.

The more recent literature on bubble velocity has been reviewed by Akbar and Ghiaasiaan [10]. They observed that their data and those of others were well predicted by the following correlation, valid for $2 \times 10^{-4} < \mathrm{Ca} < 0.39$:

$$\frac{U_\mathrm{b}}{U_\mathrm{m}} = \frac{1}{1 - 0.61\,\mathrm{Ca}^{0.33}} \tag{7}$$

where U_m is the mixture velocity calculated from the overall gas and liquid flowrates divided by the area of the tube.

Bubble and Slug Length

Various characteristics in Taylor flow (such as pressure drop and mass transfer rate) depend on the bubble and slug sizes. Thulasidas et al. [6] developed a hydrodynamic analytical model for a unit cell (i. e., a bubble and a slug) that allowed the length ratio of bubble to unit cell to be calculated when the superficial gas and liquid velocities, calculated by dividing gas and liquid flowrates, respectively, with the channel cross sectional area, are known. The absolute lengths depend on the dynamics during two-phase contact made at the inlet. Thus, inlet geometry is expected to affect slug and bubble length.

Kreutzer [11] suggested a correlation for the slug length, L_s, based on experimental data in a 200 cpsi monolith reactor

$$\frac{L_\mathrm{S}}{d} = \frac{\varepsilon_\mathrm{l}}{-0.00141 - 1.556\,\varepsilon_\mathrm{l}^2 \ln(\varepsilon_\mathrm{l})} \tag{8}$$

where ε_l is the liquid volume fraction.

Akbar and Ghiaasiaan [10] conducted computational fluid dynamics simulations to model a unit cell (one bubble and two half-liquid slugs) in a capillary of 1 mm diameter. Their numerical results, as well as experimental data from previous investigators, were predicted well by the following equation:

$$\frac{U_\mathrm{m}^{-0.33}}{\sqrt{L_\mathrm{S}}} = 142.6\,\varepsilon_\mathrm{g}^{0.56}\left(\frac{d}{L_\mathrm{UC}}\right)^{0.42}\mathrm{Re}_\mathrm{g}^{-0.252} \tag{9}$$

where U_m is the mixture velocity, L_UC is the unit cell length, η_g is the gas volume fraction and Re_g is the gas-based Reynolds number, $\mathrm{Re}_\mathrm{g} = \rho_\mathrm{g} U_\mathrm{sg} d/\mu_\mathrm{g}$, ρ_g and μ_g are the gas density and viscosity and U_sg is the gas superficial velocity.

Extensive numerical simulations on the formation and channel flow of Taylor bubbles have also been conducted by Qian and Lawal [12] for gas and liquid superficial velocities from 0.01 to 0.25 m/s in a 1 mm capillary, for $0.09 < \varepsilon_\mathrm{g} < 0.91$, $15 < \mathrm{Re} < 1500$, $0.000278 < \mathrm{Ca} < 0.01$. The inlet configuration was varied either by bringing the two separate fluids into the channel through a T-junction or by premixing them. Interestingly, premixing resulted in shorter bubble or slug lengths. The T-inlet orientation and channel sizes, as well as the gas and liquid superficial velocities, affected the lengths. On the other hand, surface tension had only a slight effect while liquid viscosity had almost no influence. Their set of 148 data was correlated to within 10% by the following equation:

$$\frac{L_\mathrm{UC}}{d} = 1.637\,\varepsilon_\mathrm{g}^{-0.893}(1 - \varepsilon_\mathrm{g})^{-1.05}\mathrm{Re}^{-0.075}\mathrm{Ca}^{-0.0687} \tag{10}$$

Bubble and slug lengths can be obtained by multiplying Eq. (10) with the respective phase volume fractions.

Systematic experimental investigations on the effect of the inlet configuration on the bubble size have been carried out by Amador et al. [13]. T- and Y-junctions with different inlet channel dimensions and fluid joining angles were used as well as a co-flow configuration with the gas in the middle and the liquid in the annulus around it. Three bubble formation mechanisms were identified. In some cases bubble pairing was also observed at the inlet. The bubble length was found to depend mainly on the ratio of the

gas to liquid superficial velocities. The size of the gas inlet affected the bubble size but the size of the liquid inlet or the angles at which the fluids joined only had a small effect.
The importance of the gas and liquid flowrates on the size of the bubbles formed in a T-junction, was confirmed by Garstecki et al. [14]. Based on scaling arguments they derived the following expression:

$$L_B/w = 1 - \alpha(Q_g/Q_l) \qquad (11)$$

where L_B is the bubble length, w is the main channel width, α is a fitting parameter of order 1, Q_l and Q_g are the liquid and gas flowrates.

Pressure Drop

Bretherton's analysis also provided an expression for the pressure drop over the entire length of the bubble

$$\Delta P = 7.16\,(3\,\mathrm{Ca})^{2/3}\frac{\gamma}{d} \qquad (12)$$

From numerical simulations Kreutzer [11] derived the pressure drop in a unit cell comprised of a bubble and a slug. At low values of Ca the numerical results were slightly higher than Bretherton's predictions. Simulations indicated that the pressure drop increases with increasing Re and decreasing Ca, while with increasing Ca the effect of inertia on the pressure drop reduces. The extra pressure drop caused by the bubble could be estimated by subtracting the contribution of the liquid flow in the slug from the overall pressure drop. It was found that this extra pressure drop was almost equal to the difference in the interfacial pressure between the tips of the bubble at low Re while at high Re the dramatic increase in the pressure drop over the interface was not reflected in the overall unit cell pressure drop. A strong dependence of the pressure drop on the slug length was found experimentally. Assuming that the overall pressure drop consisted of the pressure drop in the slugs plus a Laplace pressure term caused by the bubbles, the following correlation was suggested for the friction factor, f, in capillaries during Taylor flow. The equation is valid for $2\times10^{-3} < \mathrm{Ca} < 4\times10^{-2}$ and $100 < \mathrm{Re} < 900$:

$$f = \frac{16}{\mathrm{Re}}\left[1 + \alpha_1\frac{d}{L_S}\left(\frac{\mathrm{Re}}{\mathrm{Ca}}\right)^{\frac{1}{3}}\right] \qquad (13)$$

where α_1 was found from the numerical simulations to be 0.07, while a value of 0.17 fitted the experimental data better. The difference was attributed to the presence of impurities. The following equation was proposed for low values of Re:

$$f = \frac{16}{\mathrm{Re}}\left[1 + \frac{d}{L_S}\frac{0.465}{\mathrm{Ca}^{\frac{1}{3}}}\right] \qquad (14)$$

The pressure drop is then found from $\Delta P/L = 2f\rho U_m^2 \varepsilon_l/d$, where L is the channel length.

Non-Circular Channels

In contrast to circular channels there is less information available on Taylor flow in non-circular channels and most of the information that is available refers to square channels. In square channels at $\mathrm{Ca} < 0.1$ the bubble is not axisymmetric and flattens out against the tube walls leaving liquid regions in the corners which are joined by thin flat films at the sides of the channels. As Ca increases the bubble becomes axisymmetric and for high values of Ca the bubble radius reaches an asymptotic minimum value, approximately equal to 0.68 times the square channel half-width [15]. A stagnation ring forms at the bubble surface at low values of Ca, but for $\mathrm{Ca} > 0.54$ the liquid completely bypasses the bubble. In upward and downward flows complete bypass occurs at $\mathrm{Ca} = 0.5$ and $\mathrm{Ca} = 0.57$, respectively [6]. Differences were also observed in the thickness of the film and in m between the upward and downward directions. The bubble relative velocity asymptotically approached a limiting value of $m = 0.6$ at high values of Ca in both the upward and downward flows.

Examples of Applications

One of the first applications of Taylor bubbles was in flow measurements where the bubbles acted as tracers to determine the velocity of the liquid in the capillaries. Later, however, it was recognized that the presence of the film between the bubble and the wall makes the bubble velocity different from the liquid one.

T

Applications of Taylor flow in microchannels stem mainly from the good mass transfer characteristics in this flow regime. In Taylor flow the bulk liquid is separated by the gas bubbles which significantly reduces axial mixing between the liquid slugs. The liquid recirculation within the slugs for the range of Ca encountered in small channels (see Fig. 2) also improves the radial mass/heat transfer. Fast multiphase reactions that can be mass transfer limited can benefit from improved radial mixing. In fact, much of the information on Taylor flow originates from the investigation and characterization of monolithic reactors where the two fluid phases are introduced into the reactor as froth flow and pass through catalyst-coated channels in a Taylor flow pattern. The performance of operations such as liquid chromatography within tubes with absorbing walls and tubular dialysers can be improved if Taylor bubbles are

introduced in the single-phase flow because they reduce backmixing. Even microfiltration efficiencies have been found to improve when Taylor bubbles have been introduced in the liquid medium. This improvement has been attributed to pressure pulsations caused by the alternating passage of slugs and bubbles.

In the past, the low axial mixing properties of Taylor flow were used in automated analyzers, to avoid cross-talking between successive samples. The same concept applies to high throughput screening where Taylor bubbles facilitate the sequential passage of different reactants/samples through a microchannel reactor/analyzer. The enhanced heat and mass transfer rates that are possible in microchannels can enable a kinetically controlled operating regime to be established that would allow evaluation of reaction kinetics.

Investigations on Taylor flow in non-circular channels originated from flows in porous materials, for instance in enhanced oil recovery. They are also relevant to microstructured reactors and to the many monolithic systems which in many cases have non-circular reaction channels.

Definition

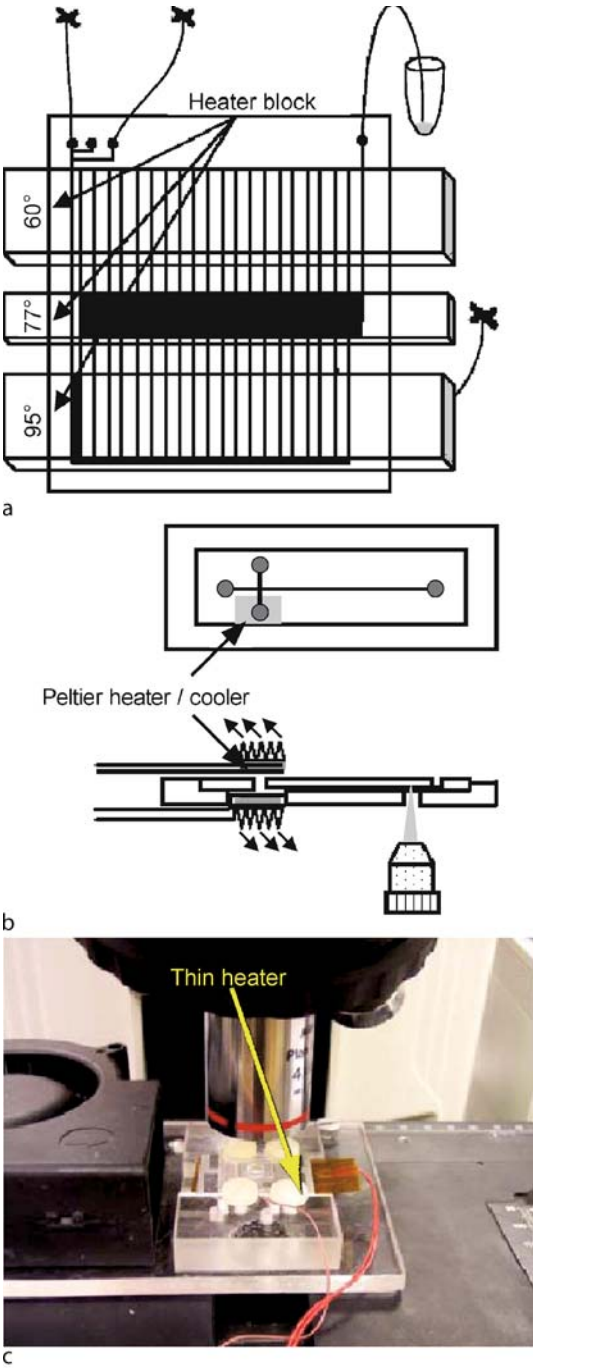
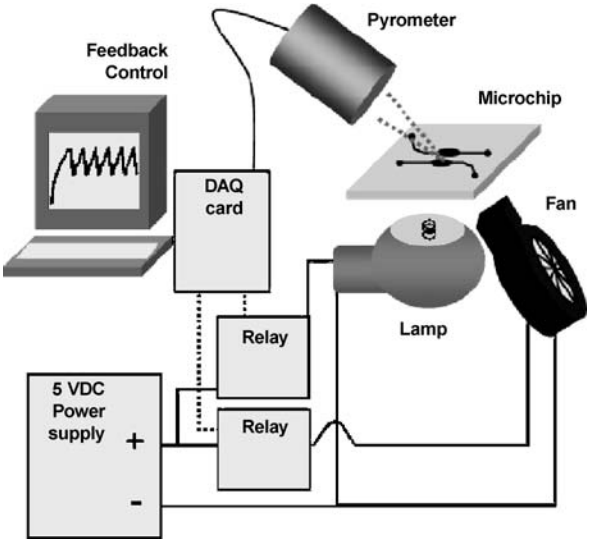
Temperature control in microfluidic systems is a way to control the temperature of fluids such as water, chemicals, and biofluids in microfluidic systems or devices by using direct/indirect heating or cooling techniques. The characteristics of the temperature control in microfluidic systems are very small control volume, shorter period of control time, small size of control areas/mass, and small size of control devices.



Temperature Control in Microfluidic Systems, Figure 1 Contact external heating methods for microfluidic devices: (**a**) heat exchanger heater [1], (**b**) Peltier thermoelectric heater [2], and (**c**) thin resistive heater [3]



Temperature Control in Microfluidic Systems, Figure 2 Infrared noncontact external heating methods for microfluidic devices [4]

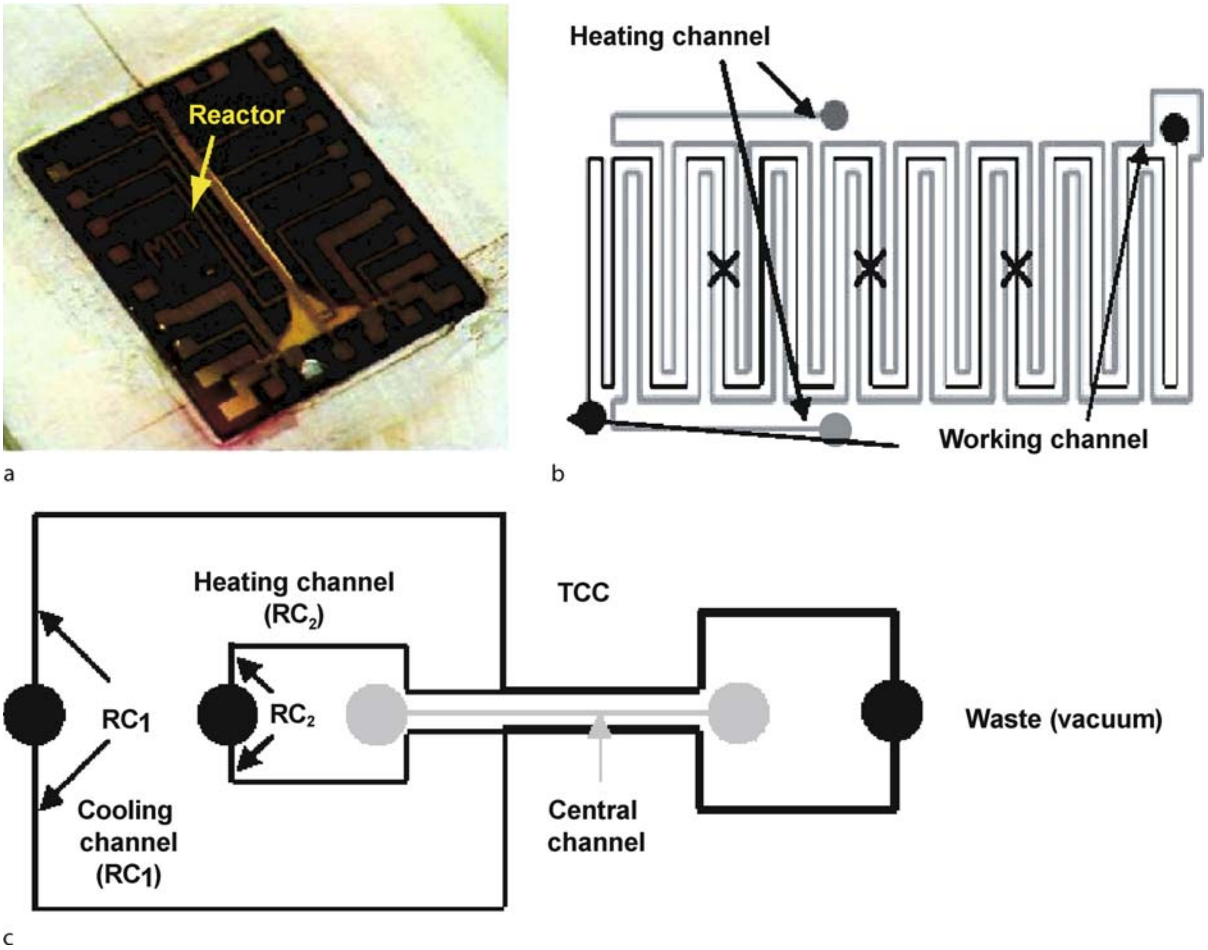
Overview

Due to smaller sample volumes and larger surface-to-volume ratios, the thermal control of microfluidic systems shows many advantages such as small amount of energy, simpler control system, and shorter control time. Precise control and rapid thermal control are also required in certain processes such as the polymerase chain reaction (PCR).

These temperature control techniques for microfluidic devices can be divided into two categories: external temperature control and internal temperature control. External temperature control systems control temperature by using external heating and cooling elements such as a heater and fan and a thermoelectric heater–cooler. Internal temperature control systems achieve heating and cooling with a thermal system embedded in microchannels.

External Heating Technique

The external heating technique relies on heating working fluids in a microchannel with separated heating elements. This is also divided into two types by heat transfer methods: contact and noncontact.



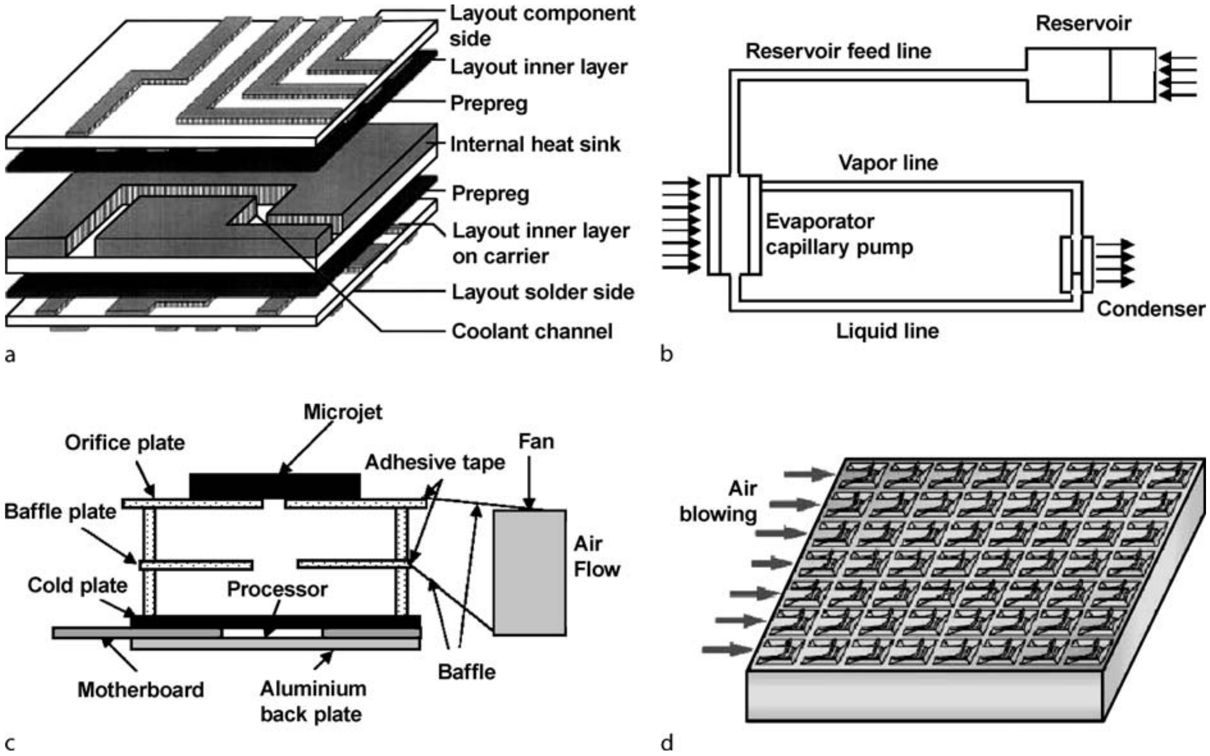
Temperature Control in Microfluidic Systems, Figure 3 Internal heating methods for microfluidic devices: (**a**) micromachined reactor [5], (**b**) Joule heating heater [6], (**c**) endothermic/exothermic heater [7]

In contact-type heating (Fig. 1) one clamps or glues heating elements on the surfaces of channels or containers which contain working fluids and heat is transferred into the fluids by conduction from the heating elements. Heat exchanging [1] by contacting the microsystem to the passively heated or cooled surfaces is widely used to control temperature. However, it is too bulky and limits are involved in integrating a microsystem. The Peltier thermoelectric heater–cooler system [2] is an example of this heating technique. The Peltier heater–cooler is a small solid-state device that functions as a heat pump. It is a sandwich formed by two ceramic plates with an array of small bismuth telluride cubes in between. When a DC current is applied, heat is moved from one side of the device to the other – where it must be removed with a heat sink. The cold side is commonly used to cool an electronic device. If the current is reversed, the device becomes a heater. Another example of contact-type heating involves temperature control by resistive heating elements [3]. Heat is generated when electricity flows in the high-resistance material as in an electric heater.

Noncontact-type heating allows heat transfer by noncontacting methods to fluids such as radiative and ultrasonic heating. Infrared temperature control [4] is a noncontact heating technique, which uses the infrared excitation of a vibration band of water combined with a high-power halogen light bulb and an optical filter (Fig. 2).

Internal Heating Technique

The internal heating technique incorporates heating elements in microfluidic devices to control temperature of fluids. A widely used technique is direct fabrication of a heater or reactor [5] inside of a microchannel or chamber. This requires a microfabricating process to manufacture



Temperature Control in Microfluidic Systems, Figure 4 Cooling methods for microelectronic or integrated electronic circuits/chips: (**a**) integrated microcooling with microchannels etched on the back of chips [8], (**b**) microcapillary pumped loop cooling [11], (**c**) microjet cooling [12], and (**d**) microfin array cooling [13]

the microheater system to fit in the microscaled container. In electrokinetically driven microflow, naturally generated Joule heating in the channel is used to control the temperature of fluids [6].

Guijt et al. [7] suggested an on-chip heating and cooling technique by using endothermic or exothermic processes in a microchannel to cool or heat solutions within an adjacent sample channel. Chemical or physical processes of solutions in a channel such as evaporation of acetone and exothermic dissolution of H_2O_4 in water are used to cool and heat an adjacent channel (Fig. 3).

Cooling

Currently the most popular cooling method is the externally controlled passive cooling technique using traditional convection heat transfer and heat exchanging techniques such as fins [1], a fan [3], and compressed air for microfluidic device cooling. Integrated cooling techniques for microfluidic devices are very limited such as the Peltier thermoelectric cooler [2] and endothermic cooler [7] mentioned above.

There are several techniques (Fig. 4) for heat removal for microelectronics or integrated circuits or chips not involving microfluidic devices. These techniques may be possible to apply for microfluidic system cooling in the near future. Integrated microcooling flowing water through microchannels etched on the backs or sides of electronic chips is used for heat dissipation in high energy generating electronic components [8]. High-efficiency evaporative heat transfer is applied for heat dissipation of electronic devices: thermosiphons [9], heat pipe cooling [10], and capillary pumped loops [11]. Air-based microelectromechanical devices such as air microjets [12] and microfin arrays [13] also effectively remove heat from microelectronic devices.

Temperature Effects on the Zeta Potential

ROBERTO VENDITTI
Department of Mechanical and Industrial Engineering, University of Toronto, Toronto, ON, Canada
roberto.venditti@gmail.com

Definition

The ► zeta potential (ζ) depends on the surface charge that appears at the interface of a liquid:solid pair when the two are brought into direct contact. The zeta potential represents the electrical potential generated as a consequence of this electrical surface charge. The zeta potential is normally treated as being invariant with respect to temperature, but recent experiments have suggested that this is not always accurate. It is important to have a precise estimate of ζ because calculation of ► electroosmotic flow velocity in a microchannel (using the ► Smoluchowski equation) depends directly upon this value.

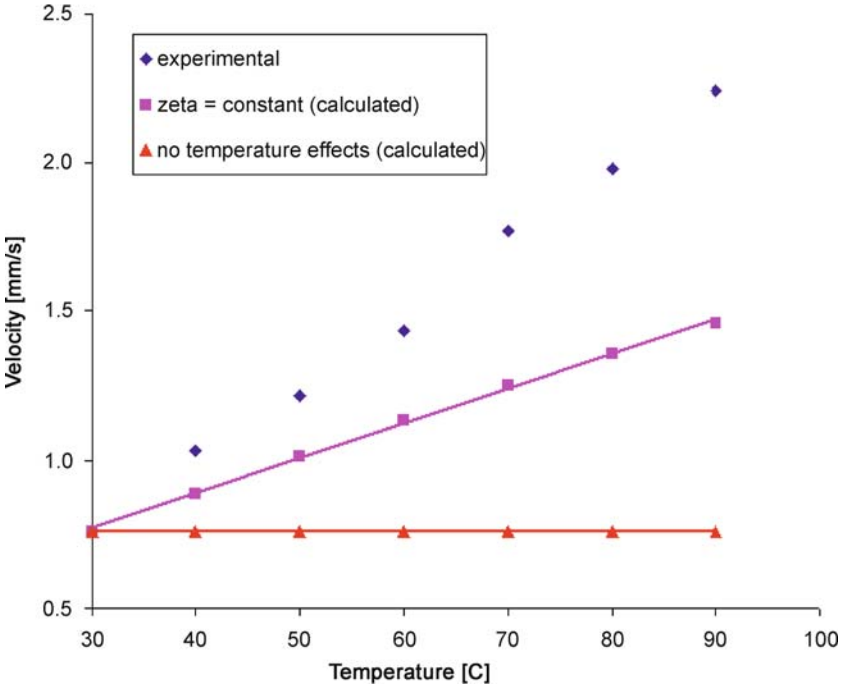
Overview

When a solid surface is in contact with an aqueous solution, a thin region of nonzero net charge density forms near the interface. The arrangement of the charges at the solid–liquid interface and the balancing counterions in the liquid is usually referred to as the electrical double layer (EDL). There is a thin layer of counterions immediately next to the charged solid surface, called the compact layer. The counterions in the compact layer are immobile due to strong electrostatic attraction. Counterions outside the compact layer are mobile. This part of the EDL is called the diffuse layer. The zeta (ζ) potential is the electrostatic potential at the boundary dividing the compact layer and the diffuse layer [2].

Application of an external electric field along a microchannel exerts a force on the EDL which can be used to drive fluid motion. This method is commonly referred to as electroosmotic flow (EOF). EOF is one of the most popular methods used to induce fluid motion in microfluidic systems (the other being pressure-driven) because it has many advantages, particularly by way of offering precise control over liquid motions.

When measured at elevated temperatures, experimentally-observed EOF velocities of liquids in microchannels are sometimes considerably higher than those predicted analytically using the *Smoluchowski equation* [1, 2],

$$U_{\text{av}} = \left(\frac{\varepsilon_r \varepsilon_0 \zeta}{\mu}\right) E_z \tag{1}$$



Temperature Effects on the Zeta Potential, Figure 1 Average electroosmotic flow velocity in a 300 μm × 8 μm PDMS : Glass microchannel filled with 10 mM KCl solution under an applied electric field, E_Z, of 15,900 V/m: (◇) experimentally measured velocity, (□) velocity calculated by Eq. 1, with temperature dependence of viscosity and permittivity considered (but not zeta potential) and (△) velocity calculated by Eq. 1, with no temperature dependencies taken into account

where U_{av} is the average channel velocity, μ, ε and ζ are viscosity, permittivity and zeta potential parameters, respectively, and E_z is the applied electric field strength. This equation is used to calculate the fluid velocity in channels driven by electric fields (i. e. ►electroosmotic flow). Adjusting viscosity and permittivity for temperature improves prediction, but can still be insufficient in some cases. An example of this is shown in Fig. 1, and will be explained in more detail shortly.

It has been demonstrated that the difference between measured and calculated EOF velocities can be adequately explained by treating the zeta potential as a temperature-dependent variable [3]. The particular relationship between ζ and temperature varies depending on the combination of buffer solution and microchannel material being used; in some cases there is a strong dependence, while in others the effect is negligible. Treating the zeta potential as a temperature-dependent variable is a relatively new idea in the field of microfluidics; the traditional approach has been to consider ζ constant over all temperatures [4]. It is important to emphasize that this is not a trivial matter; failure to account for the temperature dependence of ζ has been shown to under-predict EOF velocities by as much as 30% at the sort of elevated temperatures (∼ 90°C) that are not at all unusual in microfluidic environments (Fig. 1) [3].

The previously-described situation where in-channel fluid temperatures encountered are significantly above ambient conditions is surprisingly common in microfluidic systems. In particular, ►Joule heating effects can produce elevated temperatures in typical microfluidic channels [4]. The Joule heating phenomenon occurs in electrokinetically-driven microfluidic systems. It describes the heat generated as a result of a liquid's inherent resistance to having an electrical current passed through it. Because EOF is generated using electrical fields, current is always present and Joule heating is inevitable. In some cases the resulting elevated temperatures resulting may be sufficient to change the zeta potential to an extent whereby the effect cannot be ignored. In such cases, ζ should be taken as a temperature-dependent variable. The mathematical function used to describe this relationship should be based upon experimentally-derived results, such as those presented in [3].

The publication authored by Venditti et al. [3] describes the results of an experimental investigation that attempts to characterize the influence of temperature on the zeta potential. The work describes the experimental procedure required to measure and classify the relationship between

T

ζ and temperature for a given liquid : substrate pair. It investigates this relationship for a number of buffer solutions commonly used in the microfluidics community. The influence of buffer concentration on the ζ-temperature curve is investigated. Results are given for both glass and ► poly(dimethylsiloxane) (PDMS) substrates. The consequential effect on calculated EOF velocity is studied and shown to be significant in some cases but negligible in others.

Revil et al. [5] explain that the influence of temperature on the zeta potential is a result of changes in silanol equilibrium, adsorption equilibria, and diffuse double-layer thickness. Their analysis and data is geared towards the geophysical community, but the linear profiles they show describing change in zeta potential with temperature is consistent with [3]. A linear zeta potential-temperature profile is again reported in a more recent paper by Revil et al. [6].

A useful analysis of the effect of temperature on zeta potentials is given by Reppert and Morgan [7]. Their treatment is centred around an analysis of temperature-dependent streaming potentials, which concludes that temperature can have a significant impact on zeta potential. It can be difficult to establish how the data they offered might be applicable in a microfluidic setting, for the same reason that their work is tailored to the geophysical community.

For a thorough review of this topic, see the paper presented by Kirby and Hasselbrink Jr. [8]. This work punctuates the fact that temperature variations can have a significant impact on the zeta potential.

Owing to the vast number of buffer solutions used by the microfluidic community, there are many situations where a researcher might find it impossible to find specific information about the ζ-temperature relationship of the particular reagent being used. In such a case, it is advisable to perform a separate test to evaluate the temperature properties of the solution being used before making any assumptions about whether-or-not the zeta potential can be taken as a constant. The procedure for such an experiment is described in ► Zeta Potential Measurements section to follow.

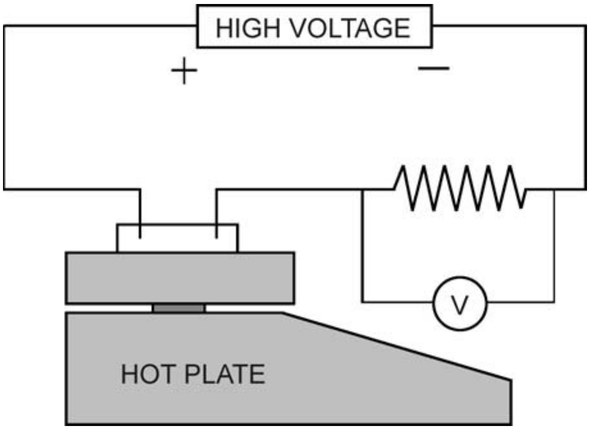
Basic Methodology

Zeta Potential Measurements

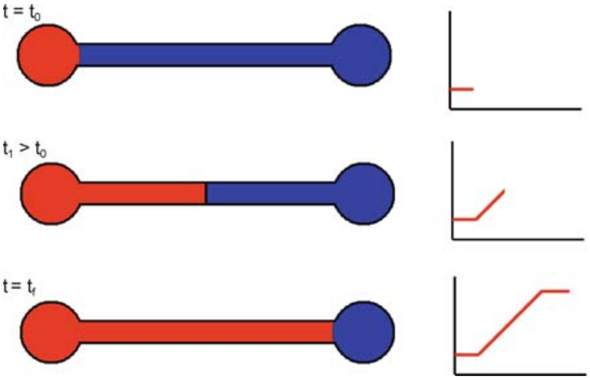
The suggested experimental setup (Fig. 2) and procedure used for zeta potential measurements is identical to that used for the time-interval current-monitoring method of Huang et al. [9]. The procedure used for measuring ζ can be described briefly as follows:

The microchannel and one reservoir are initially filled with the solution to be tested. The other reservoir is filled with a diluted version of the same buffer solution ($\sim$ 95% concentration) and a voltage is applied across the channel. Under the applied electric field, the lower concentration solution gradually replaces the higher-concentration solution. This results in a linearly-decreasing electrical current that ends in a flat plateau (which represents the instant the lower concentration buffer completely fills the microchannel). A schematic illustration of the process is shown in Fig. 3.

The electrical current is arrived at by measuring the voltage drop across a resistor positioned in series with the microchannel as a function of time. The time interval (Δt)



Temperature Effects on the Zeta Potential, Figure 2 Schematic diagram of experimental setup. Microchannel chip placed directly on hotplate surface and Platinum electrodes inserted vertically into reservoirs. Voltage drop measured across a resistor in series with the microchannel was used to calculate current flow in the electrical circuit



Temperature Effects on the Zeta Potential, Figure 3 Schematic diagram of the current-monitoring method used to measure zeta potential (ζ). As time increases, a higher-concentration buffer displaces a lower-concentration version of the same buffer solution. Consequently, the electrical current passing through the channel increases. ζ can be calculated by using the time required for the displacement process (the sloped portion of the current-time curve) in the Smoluchowski equation

required for the displacement process is measured and used to calculate the average fluid velocity, U_{av}, according to the relationship

$$U_{av} = \frac{L}{\Delta t}\,, \tag{2}$$

where L is the total length of the channel. In turn, this average velocity is used in the ►Smoluchowski equation (Eq. 1), allowing for the calculation of zeta potential by direct substitution.

A possible concern lies in determining the time interval of the displacement process. Depending on the current-time curve obtained, it can be difficult to assess the exact starting and ending points of the fluid-displacement time interval. Any error introduced into this value will affect the calculated EOF velocity (Eq. 2) and ultimately influence the calculated value of ζ (Eq. 1). Care should be taken to minimize this error by using sufficiently long displacement periods (as controlled by the applied voltage) that the reading error (typically ~ 0.5 s) represents an acceptably small portion of total experimental time.

Provided buffer concentrations are sufficiently low, parameters of permittivity and viscosity can be taken to be the same as for pure water [10]. After obtaining the current-time curve, the experiment is run again in the reverse direction. This complete process should be repeated at least once, which provides a total of four separate curves for each data point. Having repeatable results helps minimize the influence of inability to precisely evaluate the start and end points of the displacement curve.

An alternative method that can be used to calculate the value of ζ uses the slope of the current-time curve instead of its duration, as described in [2]. This method can be more accurate then the previously-described option because it avoids needing to take measurement from the beginning and ending regions of the plot. Unfortunately, it requires an accurate measurement of the buffer conductivity which can be inconvenient to obtain for the small volumes used in microfluidic systems.

To allow for temperature-dependent measurements, the fluid temperature in the microchannel must be controlled precisely. One possible method for this is to position the microchannel atop a hotplate that can be used to set and maintain precise channel temperatures. The temperature setting is increased after each experimental run and the procedure is repeated once the hot plate is allowed to reach steady-state. The solution in both reservoirs should be replaced between runs to eliminate any effects of electrochemical changes and concentration increases (due to evaporation).

Special attention must be given to the sizing of the critical elements of the experiment. In particular the resistor value should be carefully-selected to provide a measurable voltage drop for the current draw of the system in use. Using Ohm's law, a 500 kΩ resistor would provide a 1 V signal for every 2 μA of current passing through the circuit. This scenario is typically sufficient for relatively high concentration solutions (~ 1 mM) in moderately-sized microchannels ($D_h \sim 15$ μm). If solution concentration is lowered, or channel size is reduced, resistors of higher value might be required (such as 1 V per 0.5 μA) because the net current through the circuit is smaller.

Caution should also be exercised when deciding upon the channel dimensions to be used for measurement. Larger channels result in a higher electrical current that can be measured more-easily, but the higher current implies that the effect of Joule heating is enhanced. This may lead to a less stable measurement condition. Typically the smallest channel that still provides a voltage that is measurable with available equipment should be used.

Selection of the electric field to be used for experimental measurements also requires some care. In general, the voltage to be used should adhere to three experimental concerns:

- Resultant current should be sufficiently high as to be measured reliably
- but also, resultant current should be sufficiently low that no Joule heating effects are observed (i. e. electrical current stable over a span of at least 60 s).
- Experimental time interval should be long enough that reading error does not adversely effect interpretation of experimental results (typically ~ 30 s displacement time is required).

Running the experiment consecutively in opposite directions helps to eliminate any possible influence of pressure-driven flow. This ensures that measured velocity is due to the driving force of the electric field only and results in a more accurate calculation of the zeta potential. Other steps to be taken to minimize pressure-driven effects include meticulously leveling of the channel prior to experimentation, careful balancing of reservoir heights, and use of small channel heights (resulting in increased flow resistance). Large reservoirs should be used such that any change in fluid elevation caused by fluid flow during experimentation is miniscule.

Key Research Findings

From the perspective of a researcher wanting to implement temperature dependence of ζ into calculations of EOF, specific mathematical relationships are most important. For this purpose, Table 1 [3] summarizes ζ-Temperature

Temperature Effects on the Zeta Potential, Table 1 Summary of measured zeta potential results

Solution		Concentration	$\zeta(30\,°C)$ [mV]	$\zeta = \zeta(T)$[mV, °C]
	(a)	0.1 mM	– 108.2	– 0.06 T – 107.4
	(b)	1 mM	– 92.6	– 0.44 T – 78.2
KCl	(c)		(– 78.2)	(– 0.20 T – 72.8)
	(d)	10 mM	– 56.4	– 0.48 T – 43.8
	(e)		(– 38.4)	(– 0.09 T – 35.5)
1X TBE	(f)	89 mM Tris, 89 mM Boric Acid, 2 mM EDTA	– 52.4	– 0.35 T – 40.0
1X TE	(g)	10 mM Tris, 1 mM EDTA	– 68.2	– 0.01 T – 67.9
$Na_2CO_3/NaHCO_3$	(h)	10 mM	– 92.9	+ 0.02 T – 93.1

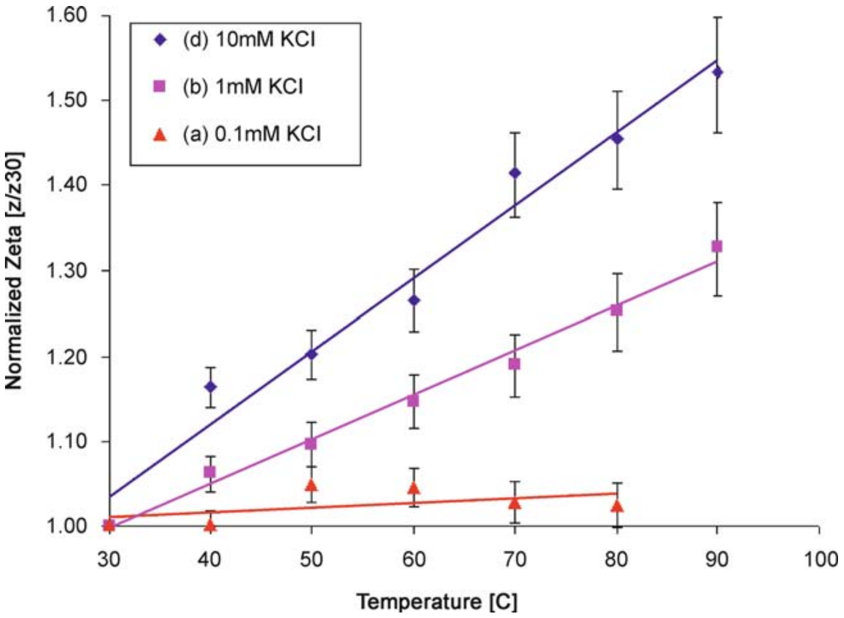
Temperature Effects on the Zeta Potential, Figure 4 Zeta potential measurements as a function of liquid temperature for a number of commonly-used solutions: (◇) 10 mM KCl, (□) 1X TBE, (△) 1X TE , and (○) 10 mM $Na_2CO_3/NaHCO_3$. All values are for PDMS:Glass microchannels and are normalized to the zeta potential measured at 30°C

relationships for a number of solutions that are commonly used by the microfluidics community. The tabulated data compares the temperature dependence for a number of different solutions, including three different concentrations of KCl. Also considered is the influence of the substrate material on the temperature dependence. Both glass and PDMS are examined, as both are highly-relevant to modern microfluidic applications. The data shown in Tab. 1 represents linear fits to experimental data, and are labeled on the other figures shown in this section. Bracketed entries denote PDMS : PDMS microchannels. All other entries represent PDMS : Glass.

Most of the figures present zeta potential values normalized to the value obtained at 30°C. This relative treatment makes it easier to directly compare solution curves that might otherwise be widely separated because of significant differences in the absolute zeta potential values. Error bars were obtained by considering that the greatest source of experimental uncertainty was present in the measurement of the time interval required for one fluid to displace the other during the current-monitoring procedure. It has been estimated that the time interval can be accurately measured within 1.0 s (i. e. ± 0.5 s). Accordingly, this information was used to calculate the range of possible zeta potential values and is reflected in the error bars shown on the figures displaying experimental results.

At this point, Fig. 1 merits further discussion. The experimental curve (◇) displays velocity data obtained by sub-



Temperature Effects on the Zeta Potential, Figure 5 Zeta potential measurements as a function of liquid temperature for a various concentrations of KCl solution: (◇) 10 mM KCl,(□) 1 mM KCl , and (△) 0.1 mM. All values are for PDMS : Glass microchannels and are normalized to the zeta potential measured at 30°C

stituting measured displacement time and channel length into Eq. 2. This particular data set shows values measured for a 10 mM KCl solution in a 300 μm × 8 μm PDMS : Glass microchannel under an applied electric field, E_Z, of 15,900 V/m. If no temperature effects are considered on any of the parameters used to calculate channel velocity (Eq. 1), the curve (△) is obtained. As expected, this plot demonstrates no dependence on temperature; it is clearly inadequate for describing the actually observed temperature-dependent velocity (◇). The next level of refinement to this is to make corrections for the known temperature dependence of the viscosity [10] [kg/m − s] (Eq. 3) and relative permittivity [10] (Eq. 4) parameters (temperatures expressed in Kelvin).

$$\mu = 2.761 \times 10^{-6} e^{\frac{1713}{T}} \tag{3}$$

and

$$\varepsilon = 305.7 e^{\frac{-T}{219}}, \tag{4}$$

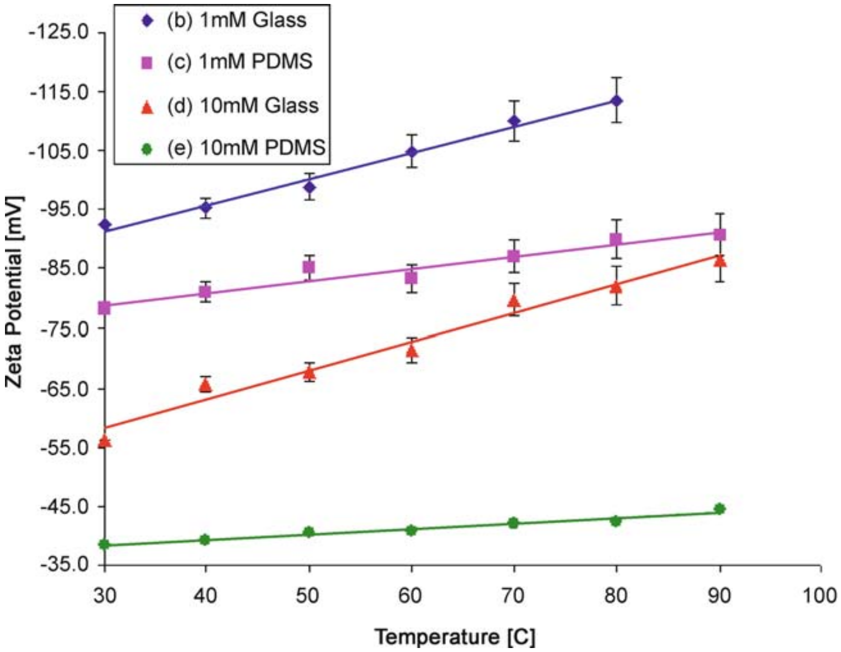
This plot is represented by the squares (□) in Fig. 1 (note that the value of the zeta potential is held constant at its room-temperature value). This treatment still fails to accurately predict the EOF velocity in the microchannel. For example, at 90°C the EOF velocity predicted by this approach would be 1.5 mm/s, while the actual velocity is 2.2 mm/s; a 32% underestimation! This plot makes it clear that in some cases the typical approach for velocity estimation is insufficient. Since the zeta potential is the only unaltered variable in the ►Smoluchowski equation (Eq. 1), it is assumed that the discrepancy is owing to inaccuracy in this variable. In these cases the zeta potential should be taken to be a temperature-dependant variable rather than a constant.

Following below are results describing the temperature variation of ζ under a number of different circumstances. Specifically, the effect of temperature on the zeta potential of different solutions is considered. Also described is the influence of buffer concentration and the effect that the substrate material may have on the relationship. The temperatures considered vary between 30°C and 90°C. This range was selected because it is believed to encompass the breadth of temperatures that one would expect to encounter in a microfluidic setting. Testing at increments of 10°C allowed for the capture of sufficient detail to provide meaningful conclusions,

T

Buffer Comparison

Figure 4 shows the results from a series of tests conducted to determine whether-or-not temperature had any influence on the zeta potential values of solutions considered important to the microfluidics community. It is surprising to note that the zeta potential of some solu-



Temperature Effects on the Zeta Potential, Figure 6 Zeta potential measurements as a function of liquid temperature for KCl solution in microchannels of either Glass substrate: (◇) 1 mM, (△) 10 mM, or PDMS substrate: (□) 1 mM, (○) 10 mM

tions is strongly-dependent upon the temperature, while others demonstrate almost no temperature influence. For this reason proper care must be exercised when assuming a constant zeta potential over a relatively large temperature span.

Concentration Effects

The concentration of the solution is also known to influence the temperature dependence of the zeta potential. Consider the following test concentrations of KCl solution: 10 mM, 1 mM, and 0.1 mM. The zeta potential of each of these solutions was measured over the range 30°C to 90°C and the temperature response was noted. The results of the concentration effect analysis are shown in Fig. 5. Results obtained clearly indicate that the zeta potential of higher concentrations (e. g., 10 mM, 1 mM) of KCl solution exhibit a strong dependence on temperature, while the low concentration (e. g., 0.1 mM) KCl shows almost no dependence. Specifically, over the same temperature span ($30-90$°C) the magnitude of the zeta potential increases by 53% in the 10 mM KCl case, 33% in the 1.0 mM case, and almost no change is seen in the 0.1 mM case. Furthermore, the results demonstrate (Table 1) that the magnitude of the zeta potential decreases as the solution concentration increases. This is consistent with the findings of other studies [1, 2, 6]. It seems that the zeta potentials of the systems with lower ionic concentration solutions are less affected by the temperature change than their higher ionic concentration counterparts.

Substrate Effects (Glass vs. PDMS)

The results presented herein are geared towards researchers using PDMS-based microfluidic chips. These devices are fabricated with either a glass or PDMS substrate. It is important to understand the influence that changing the channel substrate material has on the ζ–temperature phenomenon. Results illustrate a marked difference between the two substrate materials for different concentration KCl solutions (Fig. 6).

The observed trend for each substrate material is similar. For both substrates tested the magnitude of the zeta potential increased with solution temperature. Interestingly, the rate of change of zeta potential with temperature in the 10 mM case was much lower for the PDMS substrate than for the glass substrate. This was not seen in the 1 mM case, where the curve slope was similar for both substrates. Additionally, the magnitude of the zeta potential value was lower in the PDMS : PDMS than in the PDMS : Glass channels for both solution concentrations tested (-38.4 mV vs. -56.4 mV, and -78.2 mV vs. -92.6 mV for 10 mM and 1 mM KCl at 30°C, respectively). This result agrees with the trend observed by other groups [8] under similar conditions.

Future Directions for Research

Relatively little work has been done to characterize the effect of temperature on the zeta potential. There is much research that must still be done before we have a complete understanding of this phenomenon. The most immediate need is to conduct ζ-temperature characterization experiments for more buffers (different solutions at varying concentrations). This data will allow researchers to account for this effect in any required EOF calculations. Also required is testing in other materials used to form microchannels; silica capillaries, etched-glass, PMMA and other materials used in the microfluidics community.

A research topic of ever-increasing value is to test this effect at the nanoscale. It would be interesting to know if this phenomenon still exists in nanofluidic environments. If it does, particular relationships should be characterized and quantified.

Ultimately, the most important work still remaining is to offer a proper explanation of the phenomenon itself. Why does the zeta potential vary with temperature in some solutions, but not all? We should be able to predict which buffers will have a temperature dependent zeta potential and which will not vary. A theoretical relationship would prove most useful in avoiding the onerous task of compiling and tabulating a vast array of data covering all of the scenarios that a researcher in this field might encounter.

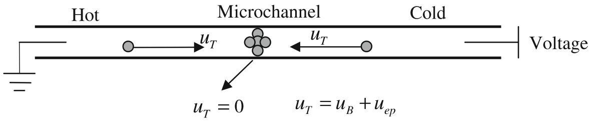
Thermal gradient focusing

Definition

Temperature gradient focusing was first reported by Ross and Locascio [1]. In principle, with an appropriate buffer having a temperature-dependent ionic conductivity, the application of a temperature gradient creates a gradient in both the electric field and electrophoretic velocities. Charged species can be stationary and concentrated at a unique point where the sum of the bulk and electrophoretic velocities is equal to zero. This means that different species, with differing electrophoretic mobilities, can be focused at spatially distinct points along microchannels or capillaries.

Overview

Separation of charged species can be achieved using capillary electrophoresis (CE), a process that utilizes the different electrical mobilities of dielectric particles/macromolecules under an applied electric field. Due to low reagent and sample consumption and high efficiency, CE has become an effective method for the sep-



Temperature Gradient Focusing, Figure 1 Schematic illustration of temperature gradient focusing in a microchannel. The microchannel is heated at one end and cooled at the other, producing a temperature gradient in the middle. The sample solute velocity u_T is the summation of two opposite velocities: the electrophoretic velocity, u_{ep} and the bulk liquid velocity, u_B. As both u_{ep} and u are a function of temperature, there exists a unique point along the channel where the sample solute velocity u_T is equal to zero. The sample solute will then move from both directions toward their respective zero-velocity points where the solutes are focused/concentrated

aration of biologically or chemically charged components, such as DNA sequencing in genetic engineering [2].

However, a typical CE-based separation suffers from relatively poor detection limits, particularly when coupled with UV absorbance detection. Consequently, CE has not been widely adopted for the analysis of drug molecules in biological fluids such as serum or urine in which the drug and its metabolites are usually at much lower concentrations than in a laboratory preparation [3, 4]. To address these problems, novel methods are needed to either improve the detection technology or increase the concentration of the sample prior to detection. For CE involving extremely short optical path lengths, the detection technology has been already pushed to its limit, thus methods of concentrating the sample prior to detection appear to be more promising [5].

Although sample extraction methods are often used to preconcentrate samples before analysis by CE, these methods increase analysis time and cost. Transient stacking, sweeping, or isotachophoresis techniques can also be used in conjunction with CE to improve the detection limits. With these types of methods, the sample is concentrated by causing the sample plug to move across a boundary between two buffers with different compositions in a capillary or microchannel. The two buffer compositions are chosen such that the analytes of interest will move more slowly through one buffer than the other. As the sample plug moves from the fast side of the boundary to the slow side, it is compressed and thus concentrated. Concentration enhancements of the order of 100 – 1000-fold are typical [6]. However, these methods are not universally applicable and often require sample pretreatment or extraction to produce a sufficiently clean sample for stacking.

Temperature gradient focusing (TGF) is a newly developed technique for spatially focusing and separating ionic analytes in microchannels or capillaries. With this method, a controlled flow of buffer is applied to the capillary to counterbalance the electrophoretic motion of the analytes. The basic mechanism of TGF is illustrated in Fig. 1. In this case, by applying a temperature gradient along the capillary filled with a buffer with a temperature-dependent ionic conductivity, a nonuniform electric field along the capillary is created. Consequently, the local flow velocity can be adjusted such that the total velocity, u_T (i. e., electrophoretic velocity, u_{ep} + bulk velocity, u) of an analyte is equal to zero at a unique point along the channel. Analytes will then move inward from both directions toward their respective zero-velocity points where the analytes are focused/concentrated.

The major limitation of microchip CE is that it requires long channels for high resolution separations, and long channels are difficult to fit into the small area of a microfluidic chip without introducing dispersion that degrades the resolution. High-resolution TGF does not require long channels; the separation presented in this study only needs relatively short capillaries (about 20 mm in length), with the separation occurring in only 4 mm of the column (a large proportion of the capillary length is required for attachment to the sample and waste reservoirs). High-resolution microfluidic chip-based TGF separations could conceivably be performed in microchannels that are only a few millimeters long, some of which could easily fit into a small, planar chip format [7].

The temperature gradient required for TGF can either be an externally applied temperature gradient or can be generated by Joule heating due to the applied electric field that also drives the focusing [1]. We will emphasize the latter. It is well known that Joule heating results from the inevitable volumetric heating when an electric field is applied across a conducting medium such as an electrolyte. Such heat would lead to an increase in the buffer temperature and develop temperature gradients in the buffer solution along both radial and axial directions of the microchannel [8]. In the following section we will present a comprehensive numerical model that describes the Joule heating-induced TGF.

Basic Methodology

To address the problems in TGF assosciated with Joule heating, computer-aided numerical simulation is needed to solve the coupled governing equations which will be presented below.

Transport of Charged Solutes

As mentioned earlier, the TGF technique is mainly used for electrophoretic concentration and separation of the solutes, and thus the transport of the charged solutes needs to be modeled. For ease of analysis, it is assumed that there is no adsorption of sample solutes onto the capillary

wall and no interaction between the sample solutes and the electrolyte components. In addition, in the vast majority of microfluidic applications, the buffer concentration is many times (100 or more) higher than that of the sample solutes, and hence, the transport equation of the charged solutes can be formulated as [9]

$$\frac{\partial C_s}{\partial t} + \left(\boldsymbol{u} + \boldsymbol{u}_{ep}\right) \cdot \nabla C_s = \nabla \cdot \left[D_s(T) \nabla C_s\right] \quad (1)$$

where $\boldsymbol{u}$ is the bulk liquid velocity (i. e., electroosmotic flow (EOF) velocity of the buffer solution) and will be described in the next section. C_s is the solute concentration and $D_s(T)$ is the temperature-dependent mass diffusivity of the solutes, given by

$$D_s(T) = D_{s0} f_D(T) \quad (2)$$

where D_{s0} is the diffusion coefficient of the solutes at room temperature, and $f_D(T)$ is a function accounting for the temperature dependence of the diffusion coefficient of the sample solutes. The electrophoretic velocity of the solutes $\boldsymbol{u}_{ep}$ can be expressed as

$$\boldsymbol{u}_{ep} = \mu_{ep}(-\nabla\phi) \quad (2a)$$

where ϕ is the applied electrical field potential. μ_{ep} is the electrophoretic mobility of the solutes, and can be written as

$$\mu_{ep} = \mu_{ep0} f_{ep}(T) \quad (2b)$$

where μ_{ep0} is the electrophoretic mobility of the solutes at room temperature and $f_{ep}(T)$ is a function accounting for the temperature dependence of the electrophoretic mobility of the solutes.

Flow Field

Since the TGF utilizes the counterbalancing bulk buffer flow (i. e., EOF) and electrophoretic motion, the flow field should be formulated. Considering the buffer solution to be a Newtonian fluid of uniform and homogeneous composition, the laminar, incompressible flow is governed by the Navier–Stokes equation

$$\rho\left(\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u} \cdot \nabla \boldsymbol{u}\right) = -\nabla p + \nabla \cdot \left[\mu(T) \nabla \boldsymbol{u}\right] - \rho_e \nabla \Phi \quad (3a)$$

$$\nabla \cdot \boldsymbol{u} = 0 \quad (3b)$$

where $\mu(T)$ is the buffer viscosity, and its dependence on temperature is expressed by $\mu(T) = 2.761 \times 10^{-6} \exp(1713/T)$. ρ and p are the solution density and hydrodynamic pressure, respectively. From Eq. (3a), it can be seen that the evaluation of the momentum equation requires a description of the net charge density, ρ_e, and the total electrical potential, Φ. It is assumed that Φ can be decoupled as the summation of the electrical double layer potential, ψ, and the applied electric potential, ϕ, as expressed in Eq. (4)

$$\Phi = \phi + \psi \quad (4)$$

Electrical Double Layer Potential

When a solid surface is in contact with an electrolyte, the surface usually becomes charged. Due to electrostatic interactions, both anions and cations are preferentially redistributed near the charged surface, leading to the formation of an electric double layer (EDL). According to the theory of electrostatics, the EDL potential distribution, ψ is governed by the Poisson equation, written as [9]

$$\nabla \cdot \left[\varepsilon(T) \nabla \psi\right] = -\frac{\rho_e}{\varepsilon_0} \quad (5)$$

where $\varepsilon(T)$ is the dielectric permittivity of the electrolyte, and its dependence on the temperature is given by $\varepsilon(T) = 305.7 \exp(-T/219)$ [10]. ε_0 is the permittivity of a vacuum.

For a symmetric electrolyte (i. e., both co-ions and counter-ions have the same charge valence, $|\sigma_+| = |\sigma_-| = \sigma$), its ionic concentration distributions for both anions and cations are assumed to follow the Boltzmann distributions [9], and hence the local charge density,ρ_e, is given by

$$\rho_e = \sigma e (n_+ - n_-) = -2\sigma e n_0 \sinh\left(\frac{\sigma e \psi}{k_B T}\right) \quad (6)$$

e is the fundamental charge, T is the absolute temperature, k_b is the Boltzmann constant, and n_0 is the ionic number concentration in the bulk electrolyte solution.

Combining Eqs. (5) and (6), we obtain the well-known Poisson–Boltzmann equation expressed as [9]

$$\nabla \cdot \left[\varepsilon(T) \nabla \psi\right] = \frac{2 n_0 \sigma e}{\varepsilon_0} \sinh\left(\frac{\sigma e \psi}{k_b T}\right) \quad (7)$$

Applied Electrical Potential

According to Probstein [9], the distribution of the applied electric potential, ϕ is governed by the Laplace equation

which is derived on the basis of the law of conservation of current and is written as

$$\nabla \cdot \left[\lambda(T)\nabla\phi\right] = 0 \quad (8)$$

where $\lambda(T)$ is the temperature-dependent electrical conductivity of the electrolyte, and is given by [10].

$$\lambda\,(T) = \lambda_+\,(T)\,\eta_+ + \lambda_-\,(T)\,\eta_- \quad (9a)$$

$$\lambda_+(T) = \lambda_{+0} f_{\lambda+}(T) \quad (9b)$$

$$\lambda_-(T) = \lambda_{-0} f_{\lambda-}(T) \quad (9c)$$

Here [$\lambda_+\,(T)$ and $\lambda_-\,(T)$] and [λ_{+0} and λ_{-0}] are the ionic conductivity of the cations and anions of the electrolyte at temperature T and room temperature, respectively. $f_{\lambda+}(T)$ and $f_{\lambda-}(T)$ are functions accounting for the temperature dependence of the ionic conductivity of the cations and anions, respectively. η_+ and η_- denote the mole concentration of the cations and anions of the electrolyte, respectively.

Joule Heating-Induced Temperature Field

The Joule heating-induced temperature field is governed by the energy equation expressed as

$$\rho c_{\mathrm{p}}\left(\frac{\partial T}{\partial t} + \boldsymbol{u}\cdot\nabla T\right) = k_{\mathrm{l}}\nabla^2 T + \lambda(T)\,(\nabla\phi)^2 \quad (10)$$

where c_{p} and k_{l} are the specific heat and thermal conductivity of the buffer solution, respectively.

In addition, a conjugate heat transfer problem has to be solved to simultaneously account for the heat transfer in the solid channel wall, which is governed by the heat conduction equation expressed as

$$\rho_{\mathrm{s}} c_{\mathrm{ps}}\left(\frac{\partial T}{\partial t}\right) = k_{\mathrm{s}}\nabla^2 T \quad (11)$$

where c_{ps}, ρ_{s}, and k_{s} are the specific heat, density, and thermal conductivity of the microchannel wall, respectively.

Initial and Boundary Conditions

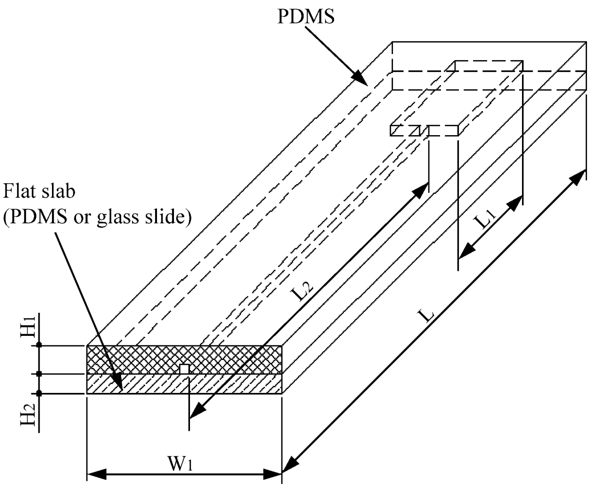
At the initial time, the microchannel is filled with an electrolyte which has the same solute concentration and temperature as the electrolyte in the inlet reservoir. The fluid is assumed to be initially stationary.

A high voltage is then imposed at the inlet reservoir, and the outlet reservoir is grounded. Due to electroosmosis, the electrolyte carrying the solutes of a given concentration is continuously injected from the inlet reservoir at room temperature, and the heated electrolyte is streamed from the microchannel to the outlet reservoir.

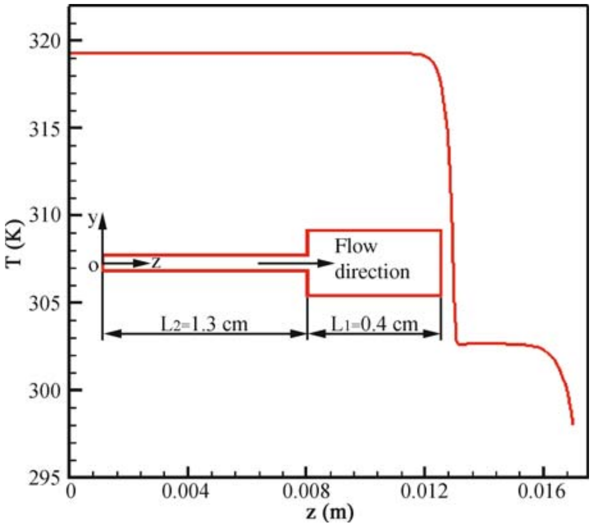
At all channel wall surfaces, the no-slip boundary condition is applied to the velocity field (the Navier–Stokes equation), the fixed zeta-potential boundary condition is imposed on the EDL potential field (the Poisson–Boltzmann equation), and the insulation boundary condition is assigned to the applied electric field (the Laplace equation), and the no-mass penetration condition is specified for the solute mass concentration field (the mass transport equation). In addition, the third-kind boundary condition (i. e., the natural convection heat transfer with the surrounding air) is applied to the temperature field at all the outside surfaces of the fabricated channels to simultaneously solve the energy equation for the buffer solution together with the conjugated heat conduction equation for the channel wall.

Key Research Findings

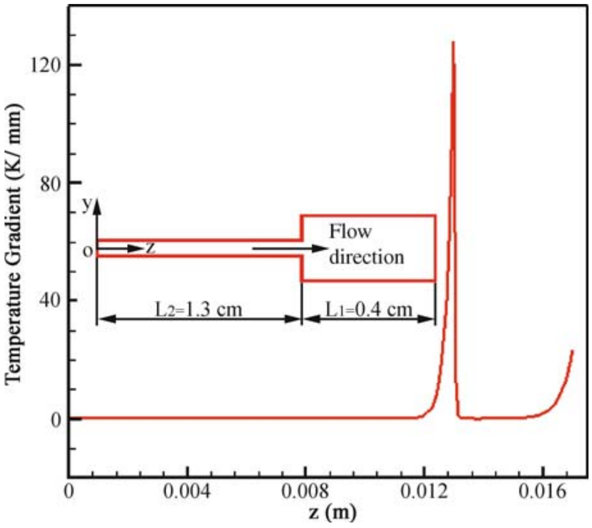
In this section, numerical simulations of the Joule heating-induced temperature field and the sample solute concentration distributions in a microchannel structure with a step change in cross-section (see Fig. 2) will be presented. Because the total current passing through a dielectric channel is constant, the current density in the narrow channel is higher than that in the wide channel. As shown in Eq. (10), the Joule heating is proportional to the second power of the current density, so more heat is generated in the narrow channel. Consequently, the temperature in the narrow channel is higher than that in the wide channel, resulting in the formation of a sharp temperature gradient at the junction. The variations in the



Temperature Gradient Focusing, Figure 2 Schematic diagram of the microchannel with a step change in cross-section



Temperature Gradient Focusing, Figure 3 Temperature variation along the centerline of the microchannel



Temperature Gradient Focusing, Figure 4 Temperature gradient variation along the centerline of the microchannel

temperature and temperature gradient along the centerline of the microchannel with a step change in cross-section are shown in Figs. 3 and 4, respectively. The microchannel is made of Polydimethylsiloxane (PDMS) sealed with another PDMS sheet. The parameters used in the simulation are similar to those reported by Ross and Locascio [1], and they are the chip dimensions ($W_1 = 7\,\text{mm}$, $L = 17\,\text{mm}$, $L_1 = 4\,\text{mm}$, $H_1 = H_2 = 2\,\text{mm}$) and the cross-sections for the narrow channel (40 μm × 30 μm) and the wide channel (300 μm × 30 μm) (see Fig. 2). The buffer solution is 20 mM $NaHCO_3$ electrolyte, the average electric field strength is $E_0 = 1000\,\text{V/cm}$, and the air natural-convection cooling mode is selected (i. e., the convection heat transfer coefficient $h = 10\,\text{W/m}^2\text{K}$). Table 1 provides the expressions for the temperature-dependent functions of the solute mass diffusivity ($f_D(T)$), solute electrophoretic mobility ($f_{ep}(T)$), and buffer electrical conductivity ($f_{\lambda+}(T)$ and $f_{\lambda-}(T)$). The numerical predictions presented in Figs. 3 and 4 are consistent with the experimental data [1]. Experimentally, it was recorded that the temperature spanned the range 23 – 39 °C (at room temperature 22 °C, with a maximum gradient of 150 °C/mm. While the numerical simulations show that the temperature varies in the range 28 – 43 °C (the room temperature in the simulation is set at 25 °C), with a maximum gradient of 140 °C/mm. Both the initial and injected sample solute concentrations are 8 μM.

Figure 5 shows the simulated sample solute concentration contours at sequential time of 0 s, 40 s, 90 s, 140 s and 190 s after the electric field has been imposed. Figure 6 displays the quantitative results of the sample solute concentrations varying along the microchannel centerline. As shown in Figs. 5 and 6, the simulations provide reasonable predictions which are consistent with the experimental results [1]. Figure 6 also shows that 190 s after the electric field has been applied, the peak of the sample concentration at the channel centerline reaches 2.8×10^{-3} M which is 350-fold the initial and injected sample concentrations. A similar value was reported by Ross and Locascio [1].

Future Directions for Research

Concentration/separation of sample solutes is one of most important functions in micro- and nanofluidic systems. TGF has proved to be a promising technique that can achieve concentration and separation in microfluidic devices. However, so far very limited experimental and theoretical investigations have been reported. Experimentally, it is highly desirable to develop various microfluidic structures that can be utilized by the TGF technique to concentrate different samples. Furthermore, more

experiments should be carried out to characterize the thermo-electrical properties of buffers and samples so as to obtain the temperature-dependent electroosmotic mobility and electrophoretic mobility, as well as buffer conductivity, viscosity and dielectric permittivity for each individual sample and buffer solution. In addition, the development of reliable, accurate, high-resolution, experimental techniques for measuring flow, temperature and sample solute concentration fields in microfluidic channels is needed. Theoretically, the model development of TGF is still in its infancy. The models presented in this study assume the dilute solute sample and linear mass flux–driving forces correlations. However, when the concentrations of the sample solute and the buffer solution are comparable, the aforementioned assumptions break down. Moreover, the channel wall zeta-potential in this situation may become nonconstant. More comprehensive models should be developed to incorporate the solute–buffer and solute–channel wall interactions as well as the heterogeneous distribution of the channel zeta-potentials.

Recent years have seen significant academic interest in nanofluidics. Fundamental research has reached a feverish level. However, no information is available on the demonstration of the TGF in nanofluidic channel structures.

Temperature control

Definition

In today's microfluidic technology, electrokinetic transport is used to perform many chemical and biological analyses in Lab-on-Chip devices, such as clinical diagnoses, DNA scanning, cell manipulation, cell patterning, and molecular detection. Due to the presence of an electrical potential gradient in electrokinetic transport, Joule heating is a ubiquitous phenomenon which may lead to an increase in the overall temperature and to temperature gradients in the transverse and longitudinal directions inside the channels. These generated temperature gradients and their control are crucial for the performance of the devices.

Overview

Simply, a temperature gradient can be generated by means of two temperature reservoirs at different temperatures at the inlet and the exit of a microchannel. However, in electrokinetic transport, Joule heating results in heat generation which can also result in temperature gradient generation in the longitudinal and transverse directions inside the microchannels due to

- the effect of the temperature reservoirs at the inlet and the exit of the channel (thermal end effects);
- the different thermal boundary conditions at the channel wall (thermostatted and thermostatted region along the channel wall);
- the cross-sectional area change along the channel; and
- the flow of two parallel streams having different molar concentrations.

These temperature gradients also affect the electrical field, flow field, and concentration field via temperature-dependent electrical conductivity, viscosity, and diffusivity. Large temperature gradients inside channels may cause band broadening and dispersion that leads to inefficient and low-quality separation for separation processes [1]. Effective dissipation of the heat generated by Joule heating is critical for reproducible and efficient separations in electrokinetically driven separation systems. These temperature gradients can also be useful for some applications such as isoelectric focusing (IEF) [2–4] and temperature gradient focusing (TGF) [5, 6]. Therefore, generation and control of the temperature generation inside the Lab-on-Chip are very important to enhance and optimize the performance of the device.

Xuan and Li [7] developed an analytical model to study Joule heating effects on electrokinetic transportation in capillary electrophoresis with thermal end effects by considering the temperature-dependent fluid viscosity and electrical conductivity. They derived closed formulas for steady-state temperature field, applied electrical potential field, pressure field, velocity field, and transient concentration field which provide fundamental understanding of effects of the temperature gradients on transport of heat, electricity, momentum, and mass species in capillary electrophoresis. They showed that Joule heating enhances the transport of samples which can provide a reduction in the analysis time for capillary electrophoretic separations. Despite the time reduction benefit, they also showed that Joule heating and thermal end effects increase the sample dispersion which leads to a lower separation efficiency. Xuan and coworkers [8, 9] also studied the same effects with temperature-dependent fluid properties, both numerically [8] and experimentally [9]. They used a caged-fluorescent dye-based visualization technique to measure the EOF velocity profile, and a fluorescence-based thermometry technique to measure the temperature profile inside the channel. They observed concave and convex velocity profiles due to distortion of the plug-like profile

T

because of the induced pressure gradients resulting from the axial temperature gradient.

Non-uniform cooling across the length of the channels can be experienced by some thermostatted portion of the channel either by

1. forced convection of the channel or
2. cooling of the channel by optical infrastructure in the detection region.

This non-uniform dissipation also results in temperature gradients inside the channel. Xuan and Li [10] studied case (1.) and Sinton et al. [11] studied case (2.) for a microcapillary.

Temperature gradients along the channel can also be used to focus different species inside the microchannel. IEF and TGF are the two methods that use this concept for focusing. Temperature generation along the channel is achieved both by using two reservoirs at different temperatures [4, 5] and by using Joule heating by means of the variable cross-sectional area along the channel [2, 3, 5, 6]. Using two parallel flow streams with different molar concentrations also results in non-uniform Joule heating and hence a temperature gradient in the transverse direction as well as the longitudinal direction. Cetin and Li [12] studied the effect of these two streams on the temperature field inside a microchannel for the potential use of this gradient in cell manipulation.

Thermometry

Definition

Thermometry is the determination of a medium's temperature as inferred from properties of a probe whose characteristics are highly dependent on temperature.

Overview

There exists a growing demand for the development of advanced diagnostics for high-precision temperature measurements at the microscale. This demand is driven by the ever-increasing use of complex microfluidic devices such as micro-total analysis systems (μ-TAS) and μ-heat exchangers. Lab-on-a-Chip devices, which integrate multiple complex laboratory functions onto a single chip-sized substrate, often require precise temperature control to maximize the productivity of chemical operations like mixing, reactions and separations. Such control becomes especially critical when electrokinetic pumping is used for driving flow through these devices, as the current flowing through the buffer solution can result in significant internal heat generation, a phenomenon known as Joule heating. Since most microfluidic-based MEMS devices utilize very high heat and mass transfer rates, a thorough understanding of their thermal transport characteristics is paramount for optimizing their design for increased performance and reliability.

Several methods exist for measurement of fluid and/or surface temperature at both the macro- and micro-scale; however, the appropriate choice of methodology is tightly coupled to the specific application under consideration. Further, the capabilities of many techniques that are commonly implemented at the macroscale are greatly challenged in microscale applications where one wishes to

not only resolve the local temperature but also *temperature gradients*. Therefore, any technique employed in this regard must not only have satisfactory spatial resolution but also excellent temporal response since dissipation of thermal gradients at the microscale occurs over extremely short time scales owing to high heat-transfer rates and large surface area-to-volume ratios. As such, obtaining accurate measurements of fluid temperature at the microscale is still a topic of intense research interest.

Until recently, temperature measurements in microfluidic systems were limited to measures of bulk fluid temperature at the inlet and outlet of microfluidic sections or simply measurement of the substrate temperature. With regard to local temperature measurements, thermocouple probes provide highly accurate measures of fluid and/or substrate temperature with excellent temporal response. However, thermocouples can often be physically intrusive and generally suffer from poor spatial resolution since most probes have a characteristic size of several microns or more. Alternatively, microfluidic devices can be fabricated with integrated microscale resistance temperature detectors (RTDs's) embedded in the substrate with spatial extents on the order of a few microns [13]. Micro-RTDs overcome the intrusiveness issues of thermocouples; however, their fabrication can be quite complex and RTDs still suffer from poor spatial resolution which limits their ability to resolve local thermal gradients. Further, while RTDs are convenient for monitoring surface temperature, they do not provide a direct measure of fluid temperature.

While local measures of temperature may suffice for some applications, many others require a detailed description of the spatial and/or temporal variations of temperature on a surface or in a fluid. ► Infrared thermography, for example, involves the imaging of the electromagnetic energy radiated by a surface in a specific infrared band which can be directly related to the surface temperature. However, while infrared thermography yields the spatial distribution of temperature on a surface, it does not provide a measure of fluid temperature In contrast, both thermochromic liquid crystals (TLCs) and ► fluorescent thermometry (a specific application of the more general laser-induced fluorescence (LIF) technique) can provide excellent measures of fluid temperature fields. Thermochromic liquid crystals are organic molecules that behave as a liquid but maintain a crystal-like arrangement akin to a solid. For a certain class of TLCs, the molecules align in a helical pattern that reflects a preferred wavelength when under white-light illumination. Since the pitch of the helical arrangement has strong temperature dependence, the wavelength of the reflected light provides a measure of temperature. Therefore, imaging of the light reflected by a suspension of TLCs in a fluid or a surface coating of TLCs can provide a measure of temperature over a given field of view. In fluorescent thermometry, a fluorescent dye whose ► fluorescence intensity is a strong function of temperature is dissolved in a fluid of interest or is coated on a surface of interest. The fluorescent dye is illuminated with incident light which excites the molecules to fluoresce at a different wavelength and this fluoresced light is recorded by a CCD camera. For many dyes, the intensity of the fluoresced light is a strong function of temperature. Therefore, imaging of the fluorescence, in concert with an a priori calibration of the fluorescence intensity with temperature, provides a measure of the temperature over the field of view. Finally, fluid temperature can be inferred by measuring the Brownian diffusion of sub-micron particles suspended in a fluid of interest since this diffusion process is known to be strongly correlated with temperature. While suitable for assessing fluid temperature, measures of Brownian motion cannot provide an estimate of surface temperature since the technique relies upon the free motion of particles suspended in a fluid.

All of the aforementioned methods certainly have many advantages and disadvantages, particularly when implemented at the microscale. Each of these methods is described in detail below and select applications of these methods at the microscale are highlighted.

Basic Methodology

Contact Temperature Sensors

Principle and Implementation

► Contact temperature sensors represent a class of probes used to infer the temperature of a medium through the thermal equilibrium attained between the sensor and the medium when in contact. In particular, changes in the medium temperature yields a corresponding variation of the sensor resistance or output voltage that can be used to infer the temperature difference via an a priori calibration of the sensor output with temperature.

Of the variety of contact sensors that exist for measurement of temperature, thermocouples are amongst the more commonly implemented probes. Temperature measurement by thermocouple is based on the principle that the contact potential generated when two dissimilar metals are in contact varies with temperature. Therefore, by measuring the difference in the contact potential of a measurement junction that forms the probe tip, relative to that of the reference junction, the temperature difference between the junctions is obtained. Thermocouples can be manufactured from many different combinations of metals, depending on the working temperature range, chemical sensitivity of the probe and desired sensitivity and

accuracy. In general, the use of thermocouples is preferred over other contact sensors because of their relatively short response times and low cost. However, the temperature sensitivity of thermocouples can be quite low ($\sim 50\,\mu\mathrm{V}/^\circ\mathrm{C}$ or less) and their accuracy is limited to approximately $\pm 0.5\,^\circ\mathrm{C}$. Further, the spatial resolution of the measurement domain is inherently limited by the physical dimensions of the probe tip that forms the measurement junction, with most thermocouple probes having a characteristic dimension of several microns or more. Therefore, the use of thermocouples for measurements of temperature at the microscale can be quite restrictive.

Resistance temperature detectors (RTDs) are contact-type temperature sensors that are based on the principle that the electrical resistance of metals increases with temperature. Therefore, RTDs are also commonly referred to as positive-temperature-coefficient sensors. Resistance temperature detector elements are typically manufactured from platinum because of the linear variation of its resistance with temperature, high stability and chemical inertness, while nickel and copper represent lower-cost alternatives. In general, while RTDs have a smaller working-temperature range than thermocouples, their increased stability and higher sensitivity ($\sim 0.35\,\mathrm{mV}/^\circ\mathrm{C}$) provide more accurate measurements of temperature (typically $\pm 0.05 - 0.1\,^\circ\mathrm{C}$). In contrast, RTDs have longer response times than thermocouples, which often renders them unsuitable for instantaneous measurements of temperature fluctuations occurring over short time intervals.

Finally, thermistors represent another class of commonly-implemented contact temperature sensors. As the name suggests, thermistors are thermally-sensitive resistors that are manufactured using semiconductor materials or transition metal oxides. The basic principle of their operation is similar to that of an RTD in that the temperature of a medium is estimated via variations in the resistance of the sensing element with temperature. However, unlike RTDs, thermistors are negative-temperature-coefficient sensors and their resistance varies inversely with temperature, often in a non-linear fashion. Although their pronounced non-linearity limits the working temperature range to within $100\,^\circ\mathrm{C}$, thermistors are known to have high temperature sensitivities ($\sim 10\,\mathrm{mV}/^\circ\mathrm{C}$), short response times and provide highly accurate temperature measurements (typically $\pm 0.02 - 0.05\,^\circ\mathrm{C}$).

Infrared Thermography

Principle

►Infrared (IR) thermography is a non-intrusive, two-dimensional technique for the whole-field measurement of surface temperature. An infrared scanning radiometer (IRSR) detects the electromagnetic energy radiated in the IR spectral band by the surface of interest and converts it into an electronic signal. For an object whose surface temperature is T, the monochromatic radiation of intensity E_λ emitted by the surface can be written using Planck's law as

$$E_\lambda = \frac{\epsilon_\lambda C_1}{\lambda^5 (e^{C_2/\lambda T} - 1)}, \tag{1}$$

where C_1 and C_2 are the first and second radiation constants, respectively, λ is the wavelength of the radiation being considered and ϵ_λ is the spectral emissivity coefficient that acts as a correction factor to account for radiation from a real surface ($\epsilon_\lambda = 1$ for a blackbody). Integrating Planck's law over the entire spectrum, from $\lambda = 0$ to $\lambda = \infty$, yields the Stefan–Boltzmann law for the total radiation intensity, E, given by

$$E = \epsilon \sigma T^4, \tag{2}$$

where σ is the Stefan–Boltzmann constant.

In general, most IRSR's are tuned to detect the radiation in a limited bandwidth of the IR spectrum and are therefore classified as long-wave (LW) radiometers or short-wave (SW) radiometers depending upon which window in the IR band is to be detected. For such cases, the radiation intensities detected by the radiometers represent intensity values integrated over the given spectral bandwidth. Temperature is then determined from these intensity values using appropriately modified forms of Eqs. (1) and (2).

Implementation

The two basic components of an IRSR are the optics that form the sensing system and the IR detector. Typically, the characteristics of the optics used in IR systems depends upon whether the incoming radiation is detected in the SW or the LW windows. For the case where the incoming SW infrared radiation is scanned, the radiometer utilizes silicon optics with a coating that has a transmittance peak at a radiation wavelength of about $5\,\mu\mathrm{m}$. Additionally, the detector is manufactured from indium-antimonide and gives a spectral response between $3.5\,\mu\mathrm{m}$ and $5.6\,\mu\mathrm{m}$. Further, a broad-band coating of the SW optics can be used to enhance the relative response of the scanner by shifting the lower limit of the SW window down to $2\,\mu\mathrm{m}$. The use of such a broad-band coating may be favorable for applications such as determining the temperature of semi-transparent objects that makes use of spectral filtering, although these systems are more susceptible to atmospheric losses. On the other hand, radiometers used in the

LW band employ germanium optics that have a peak transmission at 10 µm. The detectors used for LW radiometers are typically manufactured from mercury-cadmium-telluride and give a spectral response between 8 and 12 µm in the far infrared. While the choice of the appropriate spectral-band radiometer depends on several factors, systems operating in the LW region are generally used for higher-accuracy measurements due to relatively low atmospheric absorption. However, SW systems are preferred when the surfaces have higher emissivity factors in the SW window.

The IR detector is a transducer that converts the incoming IR radiation into an electronic signal. The most commonly used detectors are photonic detectors, where the release of electrons is directly governed by photon absorption. While photonic detectors have a very short response time (on the order of microseconds), they suffer from poor spectral response and often require cooling to temperatures well below the ambient to allow for rapid scanning, higher temperature sensitivities and lower noise levels. For most practical applications, the overall performance of an IR imaging system is evaluated using its thermal sensitivity, scan speed, image resolution and the dynamic range of the measurements that can be achieved. Typical operating temperature ranges of IRSRs span from −20 to 800 °C, and can be extended to 2000 °C using appropriate filters (the reader is referred to [1] for the specifications of commercially available IRSRs).

Thermochromic Liquid Crystals

Principle

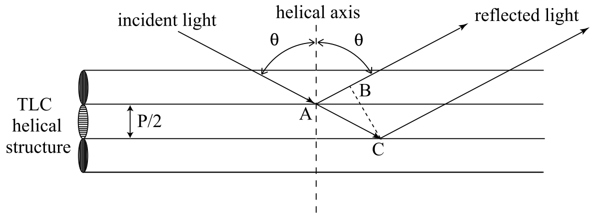
Thermochromic liquid crystals (TLCs) represent collections of long-chain organic molecules, like cholesterol derivatives, that exhibit liquid characteristics while maintaining a crystal-like order akin to a solid. Of interest from a thermometry point of view is the fact that the optical properties of TLCs strongly depend upon temperature. In particular, the wavelength of light reflected by a TLC is highly correlated with its phase (solid, liquid or intermediate) which is in turn dependent upon its temperature. At low temperatures, TLCs exist in a solid-like crystalline phase and eventually transition through intermediate phases to an isotropic liquid phase with increasing temperature. Two intermediate phases typically exist: the smectic and nematic phases. The smectic phase is achieved by heating the solid, causing the molecules to attain a layered order with their long axes oriented in a preferred direction. Upon further heating, the nematic phase is achieved wherein the layering is destroyed but the preferred orientation remains intact. In this phase, the molecules become asymmetric about their long axis, meaning they can rotate slightly with respect to one another. In this *chiral* state, the nematic phase takes the form of a helical structure wherein its pitch, p, selectively reflects white light with a wavelength on the order of p and transmits all other wavelengths. Further, the pitch of the helical structure is strongly dependent upon temperature. Therefore, the temperature of TLCs can be inferred from the hue of the light that they preferentially reflect when exposed to a white-light source.

Thermochromic liquid crystals in their raw form can provide a nearly continuous coating on a surface or a nearly continuous distribution in a solvent, meaning that the spatial resolution of the measurement is likely governed by the imaging system. Unfortunately, TLCs in this form are prone to degradation due to chemical contamination and exposure to ultraviolet (UV) and oxygen. To alleviate such issues, TLCs are typically manufactured in micro-encapsulated forms wherein the TLCs are encased within polymer shells to form discrete particles ranging in size from approximately one micron to nearly a millimeter. The polymer shell shields the TLC from contamination and most degradation issues; however, the spatial resolution of the measurement will likely be limited by the size of the encapsulated TLC particles. In addition, the thickness of the shell can distort the color reflected by a TLC and variations in shell thickness from particle to particle can produce additional variations in a given experiment. Therefore, the thickness of the polymer shell must be minimized to reduce these adverse influences.

Implementation

The experimental setup for measuring temperature via TLCs is rather simple. In a typical experiment, TLCs are either coated on a surface of interest or suspended in a liquid of interest. A white-light source is employed to illuminate a measurement region and the light reflected by the TLCs is recorded by a color CCD camera. The choice in TLCs is quite dependent upon the temperature range one wishes to resolve because the temperature range over which a TLCs reflectivity varies is a direct function of its specific chemical composition. Since it is important to maintain good contrast in recording the light reflected by the TLCs, it is common for the surface upon which the TLCs are coated or the region behind suspended TLCs to be painted black. Once a color image is acquired, the hue of the reflected light must be related to temperature. However, while this hue is strongly dependent upon temperature through the pitch of the TLC helical structure, it is also tied to other experimental parameters. In particular, the wavelength of the reflected light from a TLC is also dependent upon the angle from which the reflected light

T



Temperature Measurement, Methods, Figure 1 A schematic illustrating the interaction of TLCs with incident light (Adapted from [2])

is viewed as well as the angle and spectral composition of the incident light. Figure 1 illustrates the interaction of incident light with a repeating TLC helical structure. As discussed in [2], a path difference exists between the light reflected by consecutive helical structures given by

$$\overline{AC} - \overline{AB} = \frac{p}{2\cos\theta}(1 + \cos 2\theta) = p\cos\theta, \quad (3)$$

where θ represents the angle of the incident and reflected light (they are assumed equal for simplicity). Constructive interference will occur when

$$n\lambda = p\cos\theta, \quad (4)$$

where n is a positive integer and λ represents the reflected wavelength. Therefore, the wavelength of the reflected light is dependent upon both the pitch of the helical structure and θ. A careful calibration of the TLCs hue as a function of temperature must be performed to account for these effects. Such a calibration is achieved by placing the TLCs within an environment wherein the temperature of the TLC is known and can be precisely controlled. Images of the light reflected by the TLCs are then acquired at distinct temperature intervals from which a calibration curve relating hue to temperature can be constructed. However, given the strong dependence of the hue on both the viewing angle as well as the characteristics of the incident light, it is strongly recommended that this calibration be performed in situ to properly account for such variabilities.

While TLCs can be quite sensitive to very small temperature variations, the temperature range over which TLCs reflect from red to blue can be quite narrow, typically on the order of 1 K or less. Coupled with a typical temperature uncertainty of 0.1 K, the relative measurement error using TLCs can be larger than 10%. Further TLCs have several drawbacks for use in micro- and nano-scale devices. First, the lower bound on the size of micro-encapsulated TLCs of a few microns can limit their use in microfluidic devices of comparable size when in suspension since they would likely promote blockage. Further, the lower bound in size inherently limits the spatial resolution of the temperature measurement to a few microns. Therefore, TLCs can often be inadequate for resolving strong temperature gradients that can exist in microscale devices.

Fluorescent Thermometry

Principle

►Fluorescence refers to the process by which a fluorophore returns to its ground state through the emission of energy after absorbing a photon of a given energy. During this process, a portion of this energy is lost by the molecule before the emission occurs as it transitions between energy states, meaning that the emission is of a longer wavelength than the energy it initially absorbed. This shift in wavelength of the fluoresced light relative to the absorption wavelength is known as Stokes shift. While the emission of fluoresced light represents one possible path for the molecule to transition back to the ground state, there exist other non-radiative processes by which an excited molecule can return to its ground state. As such, the efficiency of the fluorescence emission by a dye is often quantified by its quantum efficiency

$$\phi = \frac{k_r}{k_r + k_{nr}}, \quad (5)$$

where k_r is the rate of emission of photons via fluorescence and k_{nr} represents the rate at which non-radiative relaxation to the ground state occurs. One key difficulty in exploiting fluorescence to infer temperature is that the fluorophore can sustain significant and irreversible decay of its quantum efficiency due to these non-radiative processes. In particular, repeated exposure to high-intensity incident light increases the probability of this photobleaching effect.

For a dye of concentration C (kg m^{-3}) illuminated with an incident light flux of intensity I_0 (W m^{-3}), the fluorescence energy emitted per unit volume, I (W m^{-3}), is

$$I = I_0 C\phi\epsilon, \quad (6)$$

where ϵ (m^2 kg^{-1}) is the absorption coefficient of the dye. Variations in I with temperature are predominantly attributable to a dye's quantum efficiency, ϕ, which displays some degree of temperature dependence for most organic dyes. While this temperature sensitivity is small for most dyes (typically a fraction of a percent per K), there are other dyes that exhibit significantly stronger temperature dependence, like Rhodhamine B (2.3% K^{-1}). In contrast, ϵ has a very weak temperature dependence, usually of the order of 0.05% K^{-1}. Therefore, by employing a dye whose quantum efficiency is highly-sensitive to temperature variations, the temperature distribution in a fluid

or on a surface can be inferred from intensity variations in the light fluoresced by the dye.

Single-Dye Fluorescence Temperature measurement using a single fluorescent dye is the simplest adaptation of fluorescent thermometry at the microscale. If the intensity of the illuminating light flux, I_0, is assumed constant in both space and time, then the ratio of the emitted fluorescence intensity measured at a temperature T to that measured at a reference temperature T_{ref} for a fixed dye concentration is given by the ratio of the quantum efficiencies of the fluorescent dye at these temperatures:

$$\frac{I}{I_{ref}} = \frac{\phi(T)}{\phi(T_{ref})} = f(T). \quad (7)$$

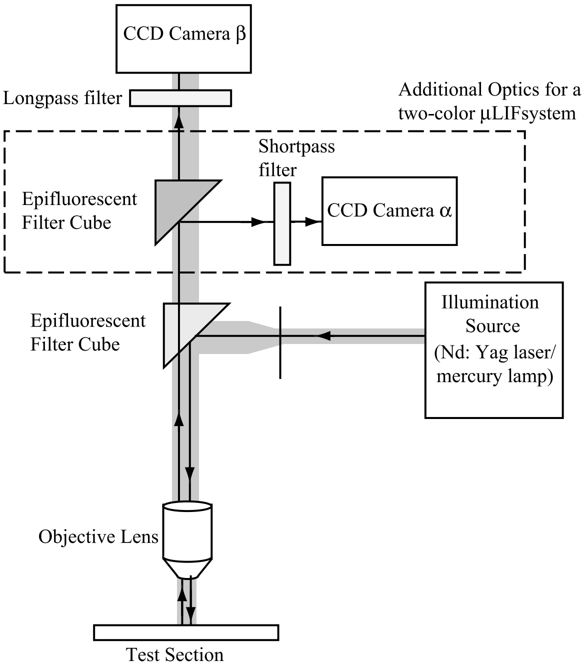
Therefore, assuming that the variation of the ratio of quantum efficiencies, or equivalently the ratio of the emitted fluorescence intensities, has been properly calibrated as a function of temperature, an estimate of the unknown temperature distribution is arrived at by comparing its fluorescence intensity to that given by the calibration. The spatial resolution of this measurement is defined by the imaging optics while the temporal resolution is defined either by the framing rate of the imaging camera or by the illumination time of the incident light.

Two-Dye Fluorescence As outlined above, the fluorescence intensity measured by single-dye fluorescence depends solely on temperature *only* if the dye concentration and the incident light flux are constant. While maintaining a constant dye concentration is quite simple, sustaining a constant incident light flux is much more difficult since all illumination sources exhibit some degree of spatial and/or temporal variability in their intensity. As such, the measured fluorescence intensity not only embodies temperature variations through ϕ, but also variations in the illuminating intensity through I_0. Therefore, the accuracy of temperature measurements via single-dye fluorescence is strongly dependent on the stability and homogeneity of the illuminating light source. To alleviate such issues, a two-dye methodology has been developed to improve the accuracy of macroscale fluorescent thermometry. In this technique, spatial and/or temporal intensity variations within the illuminating light source are accounted for via a second fluorescent dye whose quantum efficiency exhibits little, or no, temperature dependence. Therefore, while the intensity of the fluoresced light from the temperature-dependent dye embodies both variations in temperature and illuminating intensity, any variations in the fluorescence intensity of the temperature-insensitive dye are directly attributable to variations in the illuminating intensity. As such, one can account for variable illumination intensity by simultaneously imaging the fluoresced light from each dye with separate CCD cameras and normalizing the fluorescence intensity of the emission from the temperature-sensitive dye by that of the temperature-insensitive dye.

Implementation

A schematic of the imaging configuration used for the measurement of temperature via single- and two-dye fluorescence is presented in Fig. 2. Light from an illumination source, like an Nd:YAG laser, Argon-ion laser or a mercury arc lamp, is directed through an epi-fluorescent filter cube and through a microscope objective lens to excite the fluorescent dye molecules in the microfluidic device. The filter cube allows the relatively weak fluorescent signal to pass to a CCD camera while simultaneously blocking the intense illumination wavelength. Given the relatively weak fluorescent signal from the dye, the CCD camera employed must have very low noise levels and a high sensitivity to the emitted wavelength in order to maximize the signal-to-noise ratio of the measurement. In the case of two-dye fluorescence, the emissions of the two dyes must be imaged separately. Such separation is achieved by adding a second camera and additional spectral filters to the aforementioned single-dye optical arrangement (these additions are identified by the dashed bounding box in Fig. 2). In this optical arrangement, both dyes must have similar excitation wavelengths since the same illumination source is typically used to simultaneously excite both dyes. However, the dyes must have different emission spectra so that they can be effectively separated using low- and high-pass spectral filters just upstream of the cameras.

The exact temperature dependence of the chosen dye(s) must be known before the measured intensity fields for single- and two-dye fluorescence can be faithfully converted to temperature fields. This calibration is accomplished by isolating a fixed amount of each chosen dye at known concentration in a well-insulated reservoir whose temperature is both known and precisely controlled. One then maintains the dye solution at a known temperature, begins illuminating the dye solution and acquires an ensemble of images of the light fluoresced by the dye using the same optical configuration outlined above (Fig. 2). The temperature of the dye is then varied slightly and a new ensemble of images is acquired at this new temperature. This procedure is repeated until image ensembles have been acquired at several known temperatures over the range expected in a given experiment. This procedure allows one to construct a calibration curve of intensity ratio (or equivalently quantum-efficiency ratio) versus



Temperature Measurement, Methods, Figure 2 Representative schematic of the optical configuration for microscale ►fluorescence thermometry. The dashed box outlines the additional optics required for a two-dye fluorescence imaging

temperature. In the context of two-dye fluorescence, the calibration methodology is identical except that one must now assess the temperature dependence of both dyes.

Thermometry via Measures of Brownian Motion

Principle

►Brownian motion refers to the random thermal diffusion of a particle immersed in a fluid of interest due to continual collisions between the particle and the fluid molecules that are in continual, random motion. Such an effect is increasingly prevalent as the characteristic length scale of the particle decreases, meaning micron-size, or smaller, particles immersed in an otherwise quiescent fluid will display measurable diffusion owing to Brownian motion. Einstein [3] was the first to quantify the intensity of this diffusion for a spherical particle subjected to Stokes drag law in terms of the mean-square distance of diffusion defined as

$$\langle r^2 \rangle = 6D\Delta t, \tag{8}$$

where Δt is a time interval much larger than the particle response time and D is the diffusion coefficient given by

$$D = \frac{\kappa T}{6\pi \mu d_p}, \tag{9}$$

where κ is the Boltzmann's constant, T is the fluid temperature, μ is the dynamic viscosity of the fluid and d_p is the particle diameter. Combining Eqs. (8) and (9) gives

$$\langle r^2 \rangle \propto (T\mu^{-1})d_p^{-1}. \tag{10}$$

Therefore, the mean-square diffusion is proportional to the thermodynamic state of the fluid through $T\mu^{-1}$ and inversely proportional to the particle size. For fixed d_p, the mean-square diffusion is entirely defined by the thermal character of the fluid through $T\mu^{-1}$ whose temperature dependence is a function of the phase of the fluid. For a liquid, an increase in T will yield a commensurate decrease in μ, meaning that $T\mu^{-1}$ will always increase with increasing temperature. On the other hand, an increase in temperature of a gas enhances the viscosity μ, meaning that the temperature dependence of $T\mu^{-1}$ is a strong function of the specific properties of the fluid. Nevertheless, while Brownian motion can severely limit the accuracy of particle-based methods for inferring the bulk motion of a fluid at the microscale when sub-micron particles are employed (as is sometimes done in the microscopic particle image velocimetry technique), it can be used quite adeptly to infer the *thermal* character of the fluid.

Implementation

In order to determine the temperature of a fluid via Brownian motion of suspended, sub-micron particles, one must estimate the displacement of the particles owing to this random effect. There are many established methodologies for achieving such estimates, including methods for tracking the motion of single particles (particle-tracking velocimetry) as well as techniques for tracking small groups of particles (particle-image velocimetry, PIV). In both cases, the position of a particle or a group of particles must be documented at two or more times. Tracking of sub-micron particles at the microscale can be accomplished using an epi-fluorescent microscope in concert with an appropriate illumination source and a low-noise CCD camera, very much akin to the experimental arrangement used in single-dye fluorescent thermometry (Fig. 2). It is advantageous to employ fluorescently-labeled particles in conjunction with a filter just upstream of the camera that blocks the illumination wavelength and passes the light fluoresced by the particles. This experimental arrangement ensures optimal signal-to-noise ratios of the particle images. An image of the particle positions in a plane of interest in the fluid is then acquired at some time t_1 followed by a subsequent image at $t_1 + \Delta t$. The time interval, Δt, must be chosen carefully, as an underestimation of Δt will limit the diffusion of the parti-

cles while overestimation can average away the Brownian diffusion effects and can also compromise the fidelity of the tracking algorithm due to loss of particle images due to out-of-plane motion. Once time-delayed images of the particle positions are acquired, the motion of individual particles can then be assessed (particle tracking) or the motion of groups of particles in pre-defined subareas of the field of view can be tracked using statistical methods (as is done in the microscopic PIV method). Specific applications of these methodologies are presented in section *Thermometry via Measures of Brownian motion*.

Key Research Findings

Resistance Temperature Detectors

In general, most contact temperature sensors are designed to provide single-point temperature measurements, although whole-field temperature measurements may be obtained using spatially-distributed arrays of these sensors. While such measurements are fairly simple to conduct at the macroscale, performing similar measurements at the microscale can often be quite complex for several reasons. Typically, most commercially available contact sensors have probe tips whose diameters are at least of the order of a few hundred microns. This size severely constrains the maximum spatial resolution of the measurements that can be attained. Additionally, since the characteristic sizes of these sensors are of the order of the physical dimensions of the microfluidic devices under investigation, these sensors can often be physically intrusive to the flow. Further, limitations on the in-house fabrication technology of microscale temperature sensors not only limits the minimum physical dimension of the sensing element that can be fabricated but can also severely restrict the choice of sensor material. As such, these limitations affect the sensitivity and the accuracy of microscale temperature sensors in comparison to their macroscale counterparts. In particular, while micro-RTDs and micro-thermistors have shown reasonable promise as contact sensors at the microscale, these limitations have stalled development of micro-thermocouples. Watanabe et al. [12] developed a preliminary micro-thermocouple probe for the measurement of cellular thermal responses. The probe was fabricated by thermally tapering a Pyrex glass tube to produce a micropipette tip of diameter 1 μm where a 50 nm thick layer of nickel was deposited. An insulating film of diamond-like carbon (DLC) was then deposited over the nickel layer. Constantan was chosen as the second alloy to form the thermocouple junction and was deposited at the micropipette tip by ion-sputtering following the removal of a small segment of the DLC coating by focused-ion-beam etching. Although the micro-thermocouple fabricated in this manner was in its preliminary stages of validation, the authors noted that the quality of the junction at the probe tip and the decreased signal-to-noise ratio due to the higher thermal conductivity of the culture solution limited the effective sensitivity of the micro-thermocouple probe.

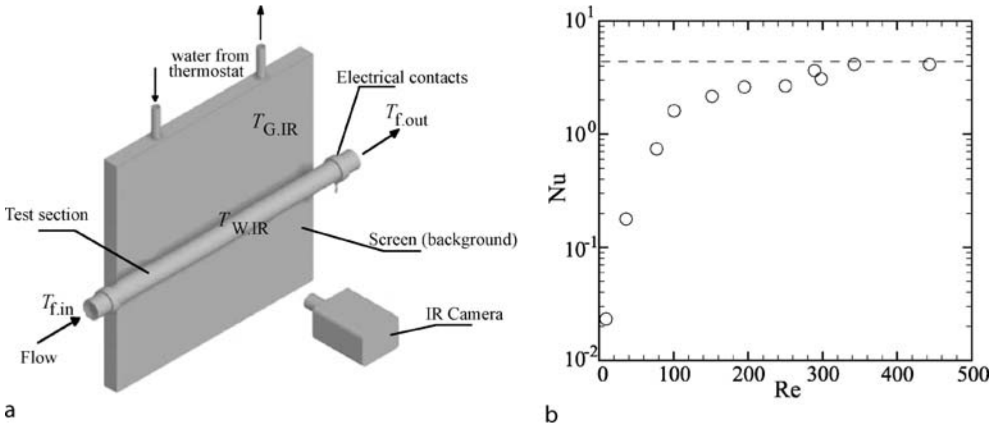
Ryu et al. [11] report the development of a micro-hotwire sensor to monitor the position and speed of advancing liquid fronts in microfluidic channels. A thin film of gold was embedded along the length of the microfluidic channel and used as the sensing element. The resistance of the sensing element as a function of temperature was calibrated and confirmed to be linear. The local fluid temperature was then assessed using this calibration information, from which the speed and position of the advancing liquid front were also determined. The temperature coefficient of the sensing element was measured to be $0.0024\,°C^{-1}$ and its thermal response time was estimated as 4 ms.

A micro-thermistor sensor array was used by Wu et al. [13] to characterize a microscale heat exchanger that utilized a series of impinging jets exiting from micronozzles. The temperature sensor chip consisted of 64 thermistor-type polysilicon sensors, each of which were 4 μm × 4 μm in dimension and were spaced 500 μm apart from one-another to form an 8×8 array in a 4 mm × 4 mm area at the center of the device. The sensors had a nominal resistance of 20 kΩ at room temperature and a temperature resolution of 0.1 °C. A polysilicon heater having a nominal resistance of 55 Ω was fabricated on the backside of the sensor chip in a manner similar to that utilized to fabricate the micro-thermistor array. Using this experimental setup, Wu et al. [13] showed that a 500 μm jet placed 750 μm above the heated surface cooled the chip from over 70 °C to nearly 35 °C.

T

Infrared Thermography

In order to obtain quantitative measurements of temperature using IR thermography, an accurate characterization of the IR system performance and its calibration must be performed prior to conducting the actual experiment. Some of the common sources of error in IR thermography include variability in the surface emissivity of the object, inaccurate mapping of the image coordinates back to the physical coordinates of the object, losses due to radiation and use of external supplementary optics. Additionally, radiation from the background can also introduce large uncertainties in the measurement of surface temperatures. This latter issue is exacerbated at the microscale where the uncertainties due to background radiation can severely limit the resolution of the measure-



Temperature Measurement, Methods, Figure 3 (**a**) Schematic of the experimental setup used for the IR temperature measurement of a capillary by [5]. (**b**) Variation of the average Nusselt number as a function of Reynolds number (Adapted from [5])

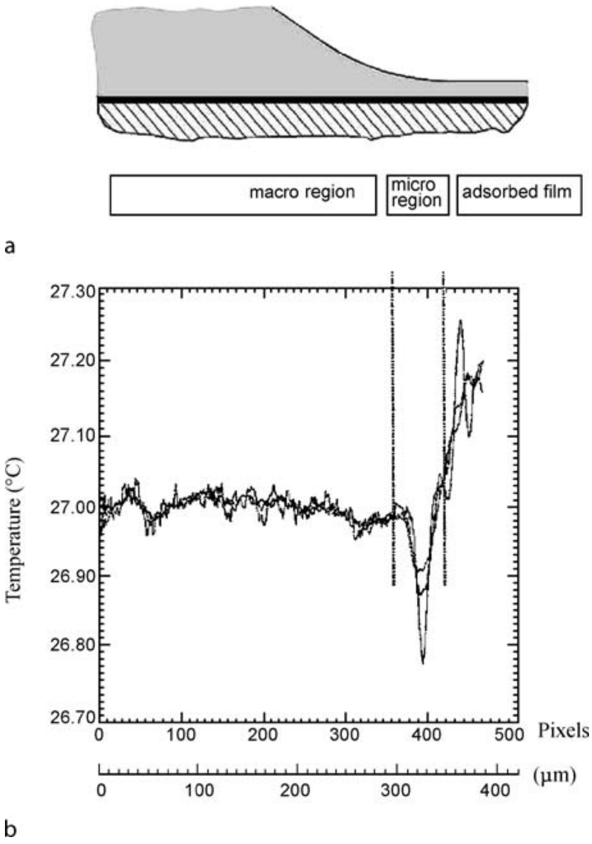
ments. The issue of obtaining accurate surface temperature measurements at the microscale using IR thermography was addressed by Hestroni et al. [5], wherein IR measurements of temperature in a 1.5 mm heated capillary are reported. Hestroni et al. [5] compensated for the background radiation by maintaining the background temperature as close to the measured temperature of the capillary surface as possible via a thermostat (Fig. 3a). A SW radiometer system with a noise-equivalent-temperature-difference of less than 0.07 K at 30 °C and an uncertainty level of 0.1 °C was utilized. Figure 3b presents the variation of average Nusselt number (Nu) with the Reynolds number (Re) of the water flow through the capillary. These results revealed heat-transfer coefficients considerably lower than that predicted theoretically for laminar flow in the range $10 < Re < 100$ through larger-diameter tubes.

Thermochromic Liquid Crystals

Höhmann and Stephan [6] utilized TLCs to study the thermal characteristics of an evaporating liquid meniscus in a capillary-driven heat-transfer device. Of particular interest were the heat-transfer characteristics in a microregion where the liquid–vapor interface approaches the boundary. Höhmann and Stephan [6] constructed a model evaporator wall consisting of a thin layer of non-encapsulated TLCs painted on a plexiglass surface followed by a thin layer of black paint. An electrically-heated metal foil was then placed upon the black surface and the evaporating meniscus was allowed to form along the foil surface. This experimental setup allowed a direct measure of the surface temperature below the evaporating meniscus by illuminating the TLCs with white light through the plexiglass and recording the light reflected by the TLCs with a three-chip CCD camera over a field of view of 640×480 µm. Use of a three-chip CCD camera allowed separate recording of the red, blue and green components of the reflected light. The authors performed a calibration in situ by maintaining a constant surface temperature, independently confirmed using thermocouple sensors at the surface, and acquiring images of the light reflected by the TLCs. This procedure was repeated for temperatures over the range of interest to calibrate the hue of the light reflected by the TLCs with temperature. Figure 4a presents an idealized schematic of the narrowing liquid–vapor interface of an evaporating meniscus and Fig. 4b presents the measured surface-temperature profile beneath the meniscus. The rapid temperature decrease characteristic of the microregion (approximately 50 µm in length) is clearly resolved in the measurement.

Fluorescent Thermometry

Temperature measurement at the microscale by single-dye fluorescence was first accomplished by Ross et al. [10] using RhB as the temperature-dependent fluorescent dye and a mercury arc lamp for illumination. Ross et al. [10] conducted measurements of fluid temperature distributions resulting from Joule heating in a microfluidic circuit (schematic presented in Fig. 5a) due to electrokinetic pumping. Figures 5b–5f present a time series of fluid temperature fields acquired by Ross et al. [10] through a constriction in the microfluidic circuit. These temperature fields clearly highlight the drastic rise in fluid temperature that can occur in the presence of electrokinetic pumping. A spatial resolution of 1 µm and a temporal resolution of 33 ms were reported, yielding temperature uncertain-



Temperature Measurement, Methods, Figure 4 (**a**) Schematic of the liquid–vapor interface characteristic of an evaporating meniscus. (**b**) Temperature profile along the surface beneath the evaporating meniscus measured with TLCs (Adapted from [6])

ties in the range 2.4 – 3.5 °C with no spatial or temporal averaging. Improved measurement uncertainties (as low as 0.03 °C) were achieved but at a significant cost in spatial and/or temporal resolution. This single-dye methodology was also employed by Erickson et al. [4] to examine Joule heating and heat transfer in electrokinetically-driven flows at the junctions of PDMS and PDMS/glass microfluidic devices. The temperature fields obtained with RhB excited by a mercury illumination source were found to agree with complementary numerical simulations to within ±3 °C. They also reported a repeatability of approximately ±2 °C and a noise level of ±1 °C. Improved noise levels were achieved by applying a Wiener-type filter to their raw image data.

Thermometry via Measures of Brownian Motion

As noted earlier, inferring fluid temperature from the Brownian motion of sub-micron particles suspended in the fluid requires an accurate estimate of the displacement of the particles over a fixed time interval, Δt. Hohreiter et al. [7] used the microscopic PIV technique to estimate the diffusion of groups of particles in pre-defined subareas of the acquired images. In its standard implementation, PIV utilizes time-delayed images of tracer particles to infer the bulk motion of a fluid by correlating subareas of the time-delayed images together. This correlation yields a peak corresponding to the average displacement of the particles in the subarea over the time interval Δt. A displacement vector (or alternatively a velocity vector when the displacement vector is divided by Δt) is then placed at the center of the subarea and the process is repeated throughout the field of view, yielding a velocity field representative of the bulk fluid motion. It is important to note that the spatial resolution of this measurement is exactly defined by the linear dimensions of the chosen subarea. Olsen and Adrian [8] noted that implementing the PIV technique at the microscale with sub-micron particles yields a broadening of the displacement peak computed from the cross-correlation of the time-delayed subareas. Hohreiter et al. [7] exploited this behavior by deriving an expression that relates changes in the cross-sectional area of the correlation peak to $\langle r^2 \rangle$ (the mean-square distance of diffusion due to Brownian motion) and hence the temperature. Hohreiter et al. [7] used this methodology to determine the temperature of a quiescent fluid from the Brownian motion of 700 nm particles suspended in water. Figure 6a presents fluid temperature inferred from the broadening of the correlation peak determined by micro-PIV analysis versus the fluid temperature measured independently with a thermocouple. The average uncertainty is reported as ±3 °C, with the uncertainty increasing slightly with temperature. It should also be noted that since the overall motion of the suspended particles is tracked via the micro-PIV process, this methodology gives one the capability of simultaneously determining *both* the bulk motion as well as the temperature of the fluid when the fluid is in motion. Simultaneous velocity and temperature measurements are particularly important when convective heat-transfer effects are substantial. Park et al. [9] present an alternate methodology for inferring temperature from particle diffusion that involves tracking the three-dimensional motion of *individual* particles using optical serial sectioning microscopy (OSSM). The OSSM technique utilizes a standard epi-fluorescent imaging setup to capture the diffraction patterns of suspended particles from which their positions in a three-dimensional space can be determined (discussion of the OSSM technique is beyond the subject of this contribution; the reader is referred to Park et al. [9] for further details). Therefore, acquisition of time-delayed images of the diffraction patterns of suspended particles enables the

three-dimensional tracking of their motion, specifically their Brownian motion when the fluid is otherwise quiescent. Figure 6b presents $\langle r^2 \rangle$ as a function of temperature for particles tracked using the OSSM technique as reported by Park et al. [9]. The authors tracked the particle motion in one, two and three dimensions and compared the measured diffusion of the particles to theoretical estimates with deviations of 5.54%, 4.26% and 3.19% reported for the one-, two- and three-dimensional measurements.

Future Directions for Research

It is important to note that most of the community's effort in the area of microscale thermometry has focused on adapting established macroscale methods for implementation at the microscale. While significant progress has been made in this regard, the accuracy of these techniques generally suffers when extended to the microscale. In the area of contact sensors, significant work remains in reducing their physical dimensions to a much less intrusive size. Even with such progress, contact sensors will always suffer from the fact that they only yield a local measure of temperature in isolation and can be highly complex when one fabricates arrays to assess spatial distributions of temperature. In contrast, methods like IR thermometry, TLCs and fluorescent thermometry overcome many of the disadvantages of contact sensors because they are ideally suited for measuring spatial distributions of temperature. Still, the accuracy of these methodologies is severely compromised at the microscale compared to their macroscale implementations due to various limitations outlined herein.

It is likely that the research community will need to consider the development of thermometry methods that are specifically tailored to the micro- and nano-scales. One such example is the development of methods relying on the Brownian motion of sub-micron particles to infer fluid temperature. While the current accuracy of this method is still comparable to most adapted macroscale methods, this technique is unique in that it relies upon a defining characteristic of particle motion at these smaller spatial scales. Another promising methodology that is specifically tailored to micro- and nano-scale systems involves the use of ►quantum dots (nanometer-scale semiconductors) as thermal markers. Quantum dots behave similarly to fluorescent dyes in that they can be excited with an illumination source to fluoresce light with rather large Stokes shifts and their fluorescence intensity is strongly dependent upon temperature. In contrast to most dyes, however, quantum dots have exceptional quantum yields (providing a significant improvement in the signal-to-noise ratio) and they do not suffer from photobleaching effects, meaning that their viability as thermal markers is not compromised by continued exposure to illuminating light.

Definition

Temperature-sensitive hydrogels, which are part of the family of stimulus-sensitive hydrogels, consist of water-filled polymer networks (i. e., gels) that display a temperature-dependent degree of swelling. Temperature-sensitive hydrogels are of interest to microactuation purposes for a number of reasons [1]: their volumetric size changes are large compared to other microactuation principles, hydrogels are soft and resilient, temperature-sensitive hydrogel actuators are operated at conveniently low temperatures and the hydrogel polymer networks can be microfabricated using standard photolithography.

Temperature-sensitive hydrogels can either display a positive temperature response, meaning that the gel material swells with increasing temperature, or a negative temperature response, meaning that the gel material shrinks with increasing temperature.

Chemical and Physical Principles

The amount of swelling of hydrogels is a function of two opposing forces. On one side water molecules moving into the hydrogel cause a swelling force, due to molecular interactions with the polymer molecules in the hydrogel. On the other side, the elastic elongation of the coiled-up polymer molecules in the polymer network results in an *elastic retractive force* opposing the swelling force in the hydrogel.

When water is added to a dry, hydrophilic polymer network (xerogel), a swelling hydrogel is formed. During the swelling process, the swelling forces dominate and the elastic retractive force gradually increases with progressive swelling. When the hydrogel is swollen to a degree that the elastic retractive forces have the same magnitude as the swelling forces, the hydrogel reaches equilibrium swelling. If the conditions of the hydrogel are kept stable, the volume of the hydrogel will remain constant indefinitely.

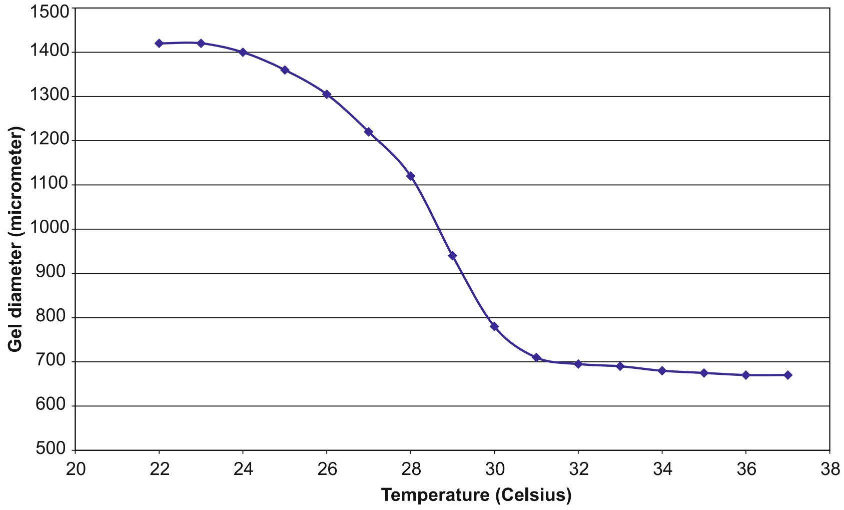
Stimulus-sensitive hydrogels have the unique property that an external physical parameter, e. g., temperature, pH or ionic strength, has an effect on the swelling forces inside the hydrogel. When the magnitude of the physical parameter is changed, the swelling force increases or decreases. As a result the hydrogel changes its degree of swelling to equilibrate the new swelling force with the elastic retractive force.

The thermal behavior of temperature-sensitive hydrogels is a direct result of the thermosensitivity of the molecular interactions between the polymer network inside the hydrogel and the aqueous solution in and around the hydrogel. In the case of a hydrogel made of poly-[N-isopropylacrylamide] (a hydrogel with a negative temperature response), the efficiency of hydrogen bond formation between the polymer and water molecules decreases at higher temperatures. At temperatures below 22 °C water molecules can form hydrogen bonds efficiently with the amide group in the polymer side chains. As a result of the efficient hydrogen bonding, water molecules move into the polymer network, resulting in the swelling of the hydrogel material. When the temperature of the hydrogel is increased to 42 °C, gradually the hydrogen bonding efficiency decreases to a minimum. This process decreases the interaction energy of the polymer network with water molecules and water moves out of the hydrogel. Macroscopically this process is visible as the shrinking of the hydrogel. Physically the temperature-dependent swelling of temperature-sensitive hydrogels can be expressed through temperature-dependent changes in osmotic pressure differences between the hydrogel and its surrounding solution. A temperature increase results in a reversal in osmotic pressure difference and water exits the hydrogel resulting in shrinking. A temperature decrease results in an increase in osmotic pressure difference and the water enters the hydrogel resulting in swelling.

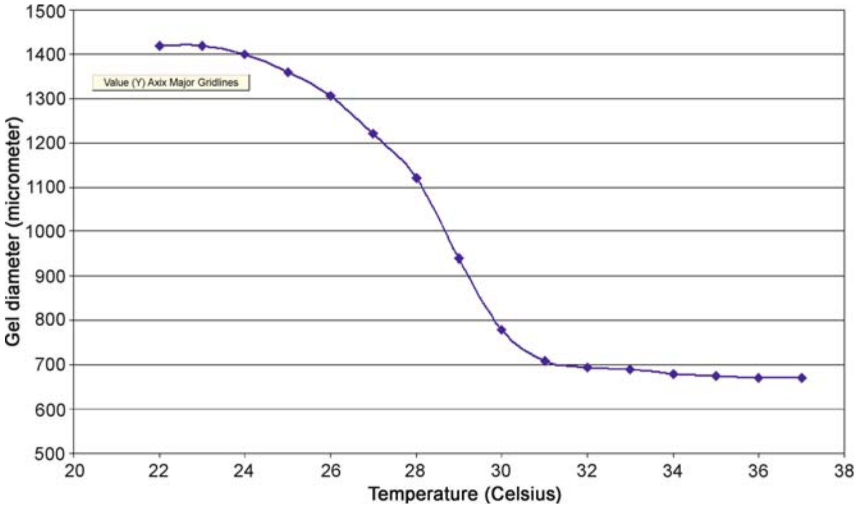
The temperature-dependent swelling behavior of these hydrogels can be represented in a graph by plotting a dimensional property of the hydrogel (e. g., the thickness or diameter of a hydrogel disc) as a function of the temperature stimulus. The resultant graph for poly-[N-isopropylacrylamide] is shown in Fig. 2.

The polymer network of temperature-sensitive hydrogels is made up of smaller repeating units called monomers. In addition to monomers, so-called crosslinker groups are present in the polymer network. The crosslinker groups form connections between different strands of polymer inside the polymer network. As a result a single giant polymer molecule is formed which is incapable of dissolving.

A commonly used monomer for the fabrication of temperature-sensitive hydrogels is N-isopropylacrylamide. This



Temperature-Sensitive Hydrogels, Figure 1 Graphical representation of the reversible swelling and shrinking of temperature-sensitive hydrogels. In the swollen state the polymer molecules in the hydrogel are strongly hydrated. The water molecules force the polymer molecules into a swollen state. In the shrunken state, the polymer molecules are attracted to each other due to the elastic retractive force (arrows), resulting in the expulsion of the water molecules



Temperature-Sensitive Hydrogels, Figure 2 Typical temperature response of a temperature-sensitive hydrogel disc made of poly-[N-isopropyl acrylamide]

monomer has the special property that it displays lower critical solution temperature (LCST) behavior and its solubility is a function of temperature. When the temperature of an aqueous N-isopropylacrylamide solution is increased above the LCST, the monomer will crystallize out of the solution. In a temperature-sensitive hydrogel this behavior is visible in the shrinking response of the hydrogel at temperatures above the LCST.

To polymerize NIPAAm into its polymer network (polyNIPAAm), free radicals are needed to initiate the polymerization reaction. Commonly these free radicals are obtained from chemical compounds called initiators. These initiators generate free radicals due to homolytic bond scission inside the initiator molecule. The bond scission can be induced by temperature or light. These initiators are called thermal initiators and photoinitiators respectively.

The swelling force of a temperature-sensitive hydrogel is a strong function of the hydrophilicity of the side groups in the polymer network. If the polymer network contains highly hydrophilic side groups, the resulting hydrogel will swell more compared to a hydrogel with less hydrophilic

side groups. Similarly, the side group hydrophilicity has an effect on the LCST of the temperature-sensitive hydrogel. The composition of the polymer network can be modified by incorporating hydrophobic or hydrophilic comonomers into the polymer network chains. When hydrophobic comonomers are incorporated, the LCST of the hydrogel will move to lower temperature regions. When hydrophilic comonomers are incorporated the opposite effect occurs. Using this method, the temperature region where a temperature-sensitive hydrogel actuator responds can be shifted to higher or lower temperatures [2]. Hence, the response of these actuators can be tailored for a specific need in an application.

Stimulus-sensitive hydrogels, such as pH-sensitive and temperature-sensitive hydrogels can be microfabricated efficiently by photopolymerization [2, 3]. This convenient process allows the use of standard microphotolithography technology (i. e., a mask aligner and photomasks) for the accurate positioning and dimensioning of stimulus-sensitive hydrogel microactuators.

A solution containing the precursors of the hydrogel network (i. e., monomers and crosslinking compounds) and a photoinitiator is deposited onto the substrate where the hydrogels should be fabricated. Using a photomask, selective areas of the precursor solution are irradiated for a sufficient time to allow the polymerization reaction to occur and a polymer network to be formed. After the photopolymerization reaction, the unreacted chemicals are dissolved, by washing the substrate in a suitable solvent. Normally within the period of 10 to 100 s, large numbers of hydrogel actuators can be fabricated with accurately defined dimensions and positions.

Examples of Application

The main focus of research on temperature-sensitive hydrogels as microactuators in microfluidic devices has been on microvalves. Hydrogel actuators have a distinct advantage for microvalve applications since they are very soft and encapsulate dust particles encountered in microfluidic flows. Normally these particles could result in the loss of function of conventional *hard* actuators when these particles get trapped in the actuator. Furthermore, temperature-sensitive hydrogel actuators are controlled by relatively small temperature changes close to ambient temperature (i. e., around 10 K to 20 K). As a result large heating powers are not necessary to control microvalves made out of these materials. Thus affording the possibility of using battery power to control the microvalves. In contrast, most conventional microactuators e. g., piezo or thermal actuators use high voltages or high power to operate.

Stimulus-sensitive hydrogel actuators display a large volume change during swelling and shrinking. Typically this volume change is around 100% to 800% for pH-sensitive hydrogels and 100% to 400% for temperature-sensitive hydrogels. Therefore a small stimulus-sensitive hydrogel actuator can be used to generate a large displacement in a microfluidic device.

Two kinds of temperature-sensitive hydrogel microvalves have been shown in the literature. The first kind of microvalve uses a monolithic piece of hydrogel, which swells and shrinks as a function of temperature to open or close a microchannel. An example of such a microvalve was shown by Yu et al. [4]. Actuation times are relatively short at 3.5 to 5 s and a holding pressure of 1.38 MPa was reported.

A second kind of temperature-sensitive hydrogel microvalve is based on the grafting of thin layers of poly-[N-isopropylacrylamide] on the surface of glass capillaries [5]. The contact angle, and thus the free surface energy, in such a treated capillary is a strong function of the temperature. By changing the temperature of the capillary, the flow of water could be controlled reversibly. The holding pressure of this kind of valve is in the range of 10 MPa.

Future Directions of Research

Because temperature-sensitive hydrogels are still a relatively new material to the field of microfluidics, their full potential in actuation applications has not been reached. It is expected that novel applications will be found where hydrogels replace standard actuators, e. g. electromagnets, but this will only be in cases where the actuation mechanism can be realized in the aqueous environment needed by the hydrogels. Additionally mechanical properties of the temperature-sensitive hydrogel materials have not been thoroughly investigated for microfluidic applications. Therefore it is necessary to both further optimize the characteristics of the actuator material and to come up with a set of design rules to allow the efficient design of temperature-sensitive hydrogel driven microfluidic applications.

Another direction of research could be the use of temperature-sensitive hydrogel thin films to allow fluid control in nanofluidics. Below the LCST these layers will be hydrophilic and above the LCST significantly more hydrophobic. It should be possible to make intelligent hydrophobic patch valves that are switched by temperature.

Temperature Sensitive Resistor

Synonyms

Hot wire; Hot film

Definition

A temperature sensitive resistor has a high enough temperature coefficient of resistance, indicating variation of electrical resistivity with temperature. A temperature sensitive resistor used for the measurement of fluid flow generally takes the form of either hot wire or hot film. When cooled by the surrounding fluid, its electrical resistance would decrease which reflects the flow rate of the fluid.

Temporal Averaging

Definition

Temporal averaging is an arithmetical averaging of local similar signals at different point of times. It has the background to increase the quality of the measurement signal and decrease the measurement noise. Using temporal averaging in image processing, several pictures (captured within a time period) are averaged. This causes a loss of temporal resolution.

Thermal Anemometer

Synonyms

Micro hot-wire anemometer

Definition

A thermal anemometer typically consists of a heater and one or more surrounding temperature sensors relative to the flow direction. The heater usually works when its self Joule heating is maintained constant. Any fluid flow through the heater will cause a shift in its temperature and thus resistance. By measuring the temperature profile around the heater, the flow rate and direction of the fluid flow can be identified.

Vapor bubbles

Definition

Thermal bubbles are those bubbles generated by heating in a liquid when its temperature exceeds its nucleation temperature.

Overview

In recent years, advances in microelectronic fabrication technology have led to many vapor-bubble actuators, such as thermal inkjet printheads, vapor-bubble micropumps, vapor-bubble perturbators and DNA microarrayers. In all of these microelectromechanical devices, microbubble(s) are generated on a microheater under pulse heating with pulse widths ranging from microseconds to milliseconds.

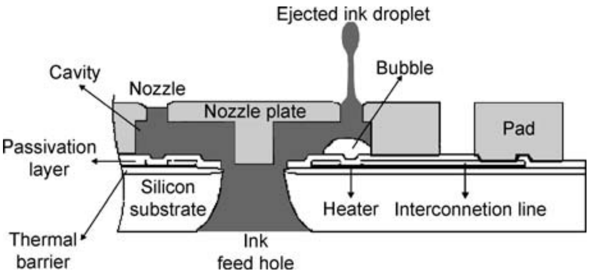
Thermal Inkjet Printheads

The thermal inkjet printhead is perhaps one of the most successful microelectromechanical systems (MEMS) products to date. The inkjet printhead uses microheaters (about $20 \times 20\,\mu m^2$ to $40 \times 40\,\mu m^2$ in size) under a train of electrical pulses of several microseconds (μs) to periodically generate microbubbles. The microbubble will expel a small droplet of ink through a nozzle at a high frequency to a specified position on a paper to compose the text and graphics. The quality of the printing depends on the thermal properties of the ink, the size of the droplets and droplet velocity, which is closely related to microbubble generation. There are three types of thermal inkjet printheads according to the direction of the ink ejection relative to the direction of vapor-bubble growth. These are: the top-shooter (also called the roof-shooter) with two directions being the same, which has been used in Hewlett-Packard's products [1]; the side-shooter, with the two directions being at right angles to each other, has been used in Canon printers [2]; and the back-shooter, with a droplet being ejected in the opposite direction to bubble growth, was first patented by Bhaskar and Leban [3].

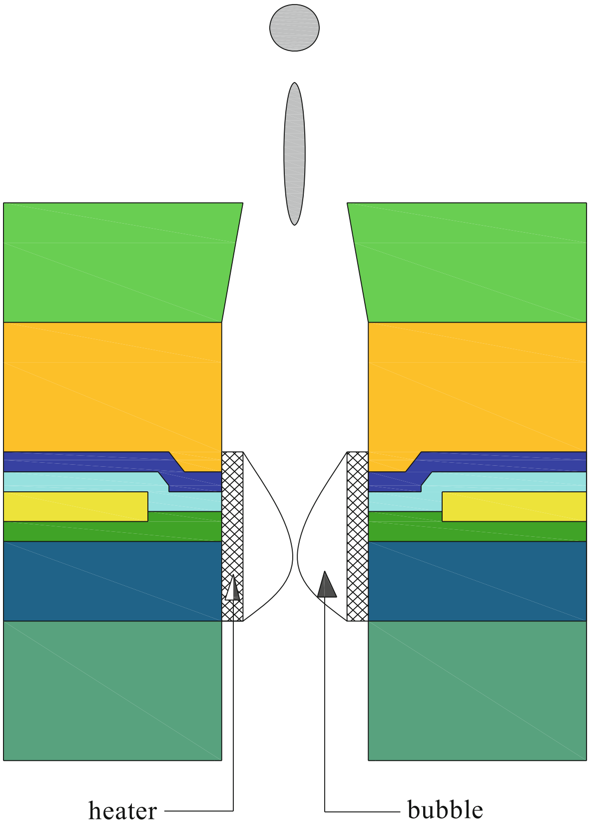
Many improved designs of the top-shooter, side-shooter, and back-shooter types of thermal inkjet printheads have recently been proposed. Lee et al. [4] fabricated a monolithic thermal inkjet printhead, which employed the top-shooter firing mode as shown in Fig. 1. The heater had an area of $40 \times 40\,\mu m^2$. The nozzles, with a diameter of 50 μm, had a resolution of 300 dpi and a nozzle-to-nozzle pitch of 170 μm. Ink ejection up to the operating frequency of 11 kHz with an average ink dot diameter of about 110 μm was achieved under current pulses of 0.3 A and 5 μs.

Baek et al. [5] have adopted two concepts to improve the nozzle density in the top-shooter design. First, the heater was placed on the sidewall of the ink inlet (see Fig. 2) and thus, the area taken by the heater could be minimized. Second, the manifold, the inlet, pressure chamber, and the nozzle were arranged in a line vertically with respect to the substrate. The nozzle density was improved in this new design although it was not easy to fabricate using MEMS technology.

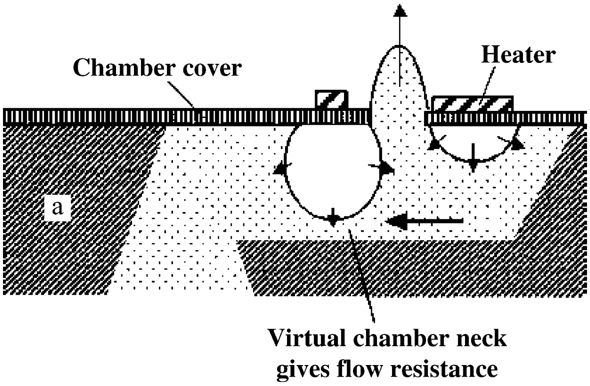
Tseng et al. [6] have introduced a modified back-shooter design, featuring two heaters with different sizes (see Fig. 3). When a current pulse passed through these two heaters connected in series, the smaller heater generated a bubble faster because of higher power dissipation. The bubble formed under the smaller heater, which can work as a virtual chamber neck, blocking the liquid passage as the larger heater started to generate its own bubble.



Thermal Bubbles, Figure 1 Cross-sectional view of the monolithic "top-shooter" inkjet printhead [4]



Thermal Bubbles, Figure 2 A “side-shooter” inkjet printhead [5]



Thermal Bubbles, Figure 3 An improved design of a “back-shooter” thermal inject printhead with two unequally sized heaters. From Tseng et al. [6]

Expansion of the second bubble pushed the ink ejection. As the two bubbles grew and eventually merged, the tail of the ejected droplet was cut off, preventing the formation of a long tail. The operation frequency of the droplet ejection with a 10 μm dimaeter nozzle was around 35 kHz.

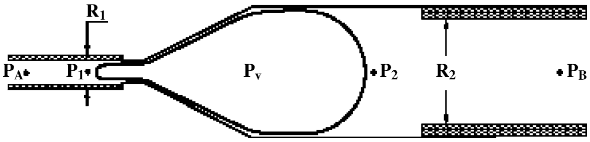
Vapor-Bubble Pumps

Geng et al. [7] have designed a novel pumping device based on the periodic generation and collapse of a single vapor-bubble in a tube. The device consisted of two stainless steel tubes with two different diameters (508 μm and 1067 μm, respectively). A divergent passage was connected from the smaller tube to the larger tubes (see Fig. 4). Pulse heating was applied at the narrow end of the divergent channel, where a vapor bubble was periodically generated and collapsed. Because of the difference in the curvature of the bubble at the narrow tube and the large tube, a capillary force was created that drove the bubble toward the larger tube according to the Young–Laplace equation. At a pulse-heating period of 100 – 1000 ms (i. e., a frequency in the range 10 – 1 Hz), the device could develop a head of a few centimeters of water with flow rates in the range of 100 μl/min.

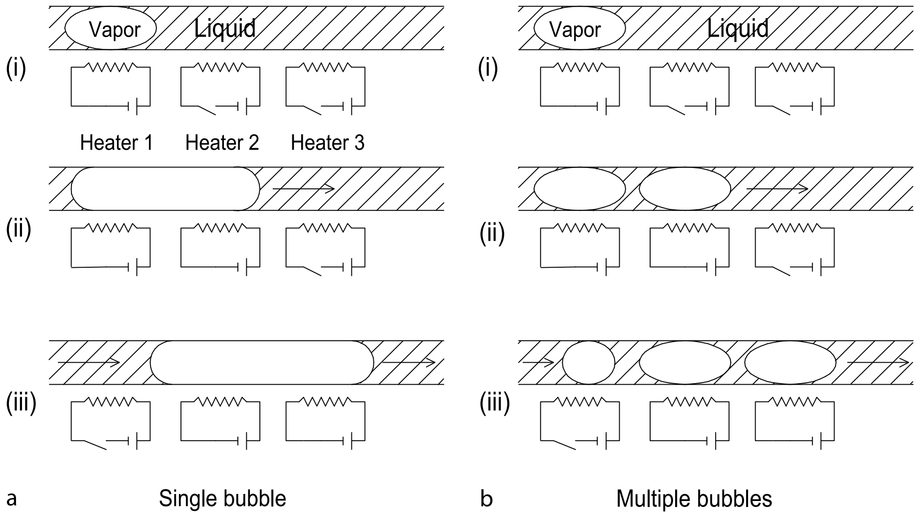
Jun et al. [8] have used the growth and collapse of a single or multiple vapor bubble(s) to displace fluids in microchannels. The pumping action was provided by asymmetric heating along the microchannels that created a variation in vapor pressure and surface tension due to the heater-induced temperature gradient. A pumping device, consisting of a microchannel with a hydraulic diameter of 3.4 μm and 726 μm in length, was fabricated in a silicon wafer. Three heaters were turned on and off sequentially (Fig. 5) to actuate the movement of vapor bubble(s). It was found that the pulse width (in the range 0.25 – 1 s) and power input (in the range 18 – 26 V) determined whether the micropump could operate in single or multiple bubble mode. Experimental results showed that pumping of isopropanol at velocities as high as 160 μm/s with a pressure head of approximately 800 Pa was achieved.

Thermal Bubble Perturbators

Lin [9] has fabricated a polysilicon microheater with nonuniform width ($10 \times 3 \times 0.5\,\mu m^3$ and $5 \times 2 \times 0.5\,\mu m^3$) to generate single microbubbles. This nonuniform microheater can induce highly localized heat source, which can generate a single microbubble periodically at the narrow part of the heater under pulse heating. Using a nonuni-

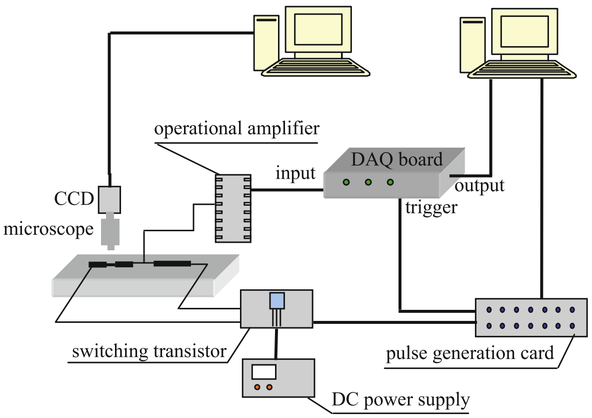


Thermal Bubbles, Figure 4 Sketch of a microbubble pump, from Geng et al. [7]



Thermal Bubbles, Figure 5 Vapor-bubble pumps for fluid displacement: (**a**) single bubble; (**b**) multiple bubbles [8]

form width microheater (with the slim part having dimensions of $10 \times 3\,\mu m^2$) under pulse heating in the millisecond range, Deng et al. [10, 11] investigated bubble growth and collapse on the microheater immersed in water as an actuator for mixing and for DNA hybridization enhancement. It was found that when single bubble was generated by pulse heating with the pulse width in the millisecond ranges, the growth and collapse of the bubble was asymmetric, leading to a net perturbation of the local fluid motion [10]. A comparison of molecular beacon-based hybridization assays with and without microbubble agitation revealed that the hybridization time could be effectively shortened by 33% with 10 cycles of microbubble agitation from a 2×1 bubble actuator array, and by 43% with 10 cycles of microbubble agitation from a 2×2 bubble actuator array [11].



Thermal Bubbles, Figure 6 Schematic diagram of experimental setup [10, 12]

Basic Methodology

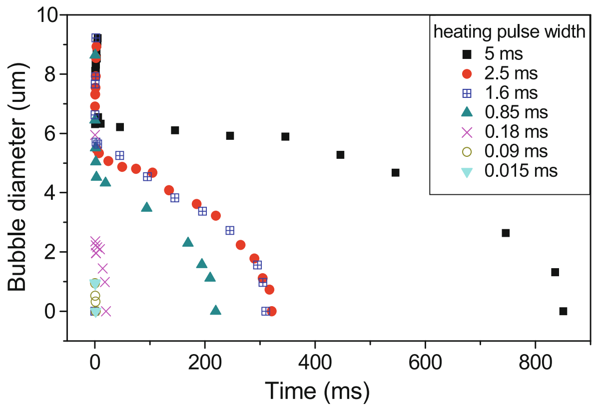
The experimental setup for the investigation of microbubble generation and its subsequent dynamics on a microheater under pulse heating is presented in Fig. 6, which shows a test section, a high-speed CCD camera, a microscope, a pulse generation system and a DC power supply. The test section consisted of a nonuniform width platinum microheater submerged in DI water, and the pulse generation system consisted of a control circuit and a switching transistor. Through the microscope and the CCD camera, with its recording process synchronized with the heating process, thermal bubble growth and collapse processes were observed. The platinum microheater was also used as a resistive temperature sensor, and the surface temperature of the microheater versus time was recorded. The temperature inflection point of the surface temperature variation curve can be identified as the nucleation temperature [12].

Key Research Findings

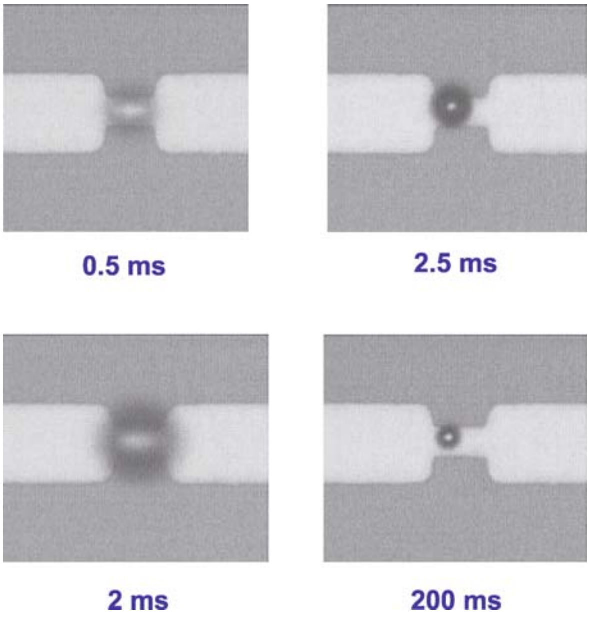
Microbubble Growth and Collapse on a Microfilm Heater

Effects of Pulse Width on Growth and Collapse Periods

The effect of pulse width (in the range 0.015 – 5.0 ms) on the bubble growth and collapse on a nonuniform



Thermal Bubbles, Figure 7 Effects of pulse width on bubble growth and collapse on a $3 \times 10\,\mu m^2$ microheater at 28.2 mW immersed in DI water [10]



Thermal Bubbles, Figure 8 Microbubble growth and collapse on a microheater at a pulse width of 1.66 ms and a power input of 28.2 mW [10]

width microheater (with the slim part having dimensions of $10 \times 3\,\mu m^2$) at a power input of 28.2 mW immersed in water is presented in Fig. 7. It is shown that the diameter of the bubble undergoes a rapid, initial growth period and after reaching a maximum value, it suddenly drops and then the bubble begins to collapse slowly as a result of the condensation process. For the short pulse widths (e. g., in the range 0.015 – 0.18 ms), a single bubble was barely observable on the surface of the microheater and the growth and collapse of the bubble was almost symmetric. When the duration of the heating pulse was in the millisecond range (0.85 – 5 ms), bubble growth and collapse periods became asymmetric with respect to time.

Asymmetric Growth and Collapse Periods and Perturbation Area

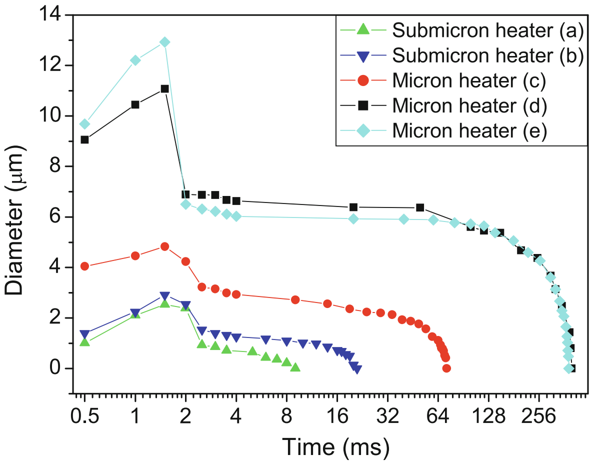
Figure 8 shows time-lapse micrographs about the asymmetric bubble growth and collapse periods on the slim part of the microheater ($10 \times 3\,\mu m^2$) at a pulse width of 1.66 ms under a power input of 28.2 mW [10]. It is shown that the bubble grew during the period 0 – 2 ms and then collapsed in the period 2 – 200 ms. The maximum size of the bubble was about 9.2 µm, which was comparable to the larger dimension of the narrow part of the microheater. To investigate the perturbation area, submicron particles (0.96 µm in diameter) were placed in the DI water near the microheater to trace the movement of the fluid, and the movement of the particles was recorded by a high-speed CCD. At such a pulse width and power input, it was found that the asymmetric growth and collapse periods of the bubble led to a perturbation area of fluid that bwas about six times greater than the maximum diameter of the bubble [10].

Effects of Heater Size on Boiling Patterns

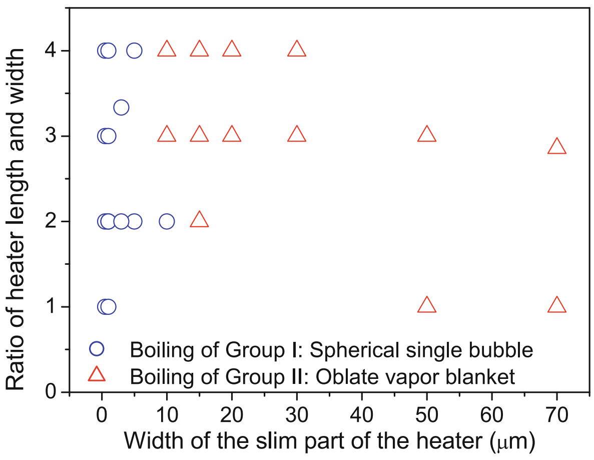
Table 1 lists the sizes of different submicron and micron heaters fabricated by Deng et al. [13] for the investigation of heater size effects on bubble shape, boiling patterns and their growth and collapse periods. A series of tests were carried out for submicron and micron heaters immersed in water at 298 K (room temperature) under a 1.66 ms pulse width. It was found that there was a critical feature size for the heater, 10 µm, for this pulse width. The boiling patterns on heaters with a feature size below or above this critical value were quite different, and they can be classified into two groups as shown in Fig. 9. A single spherical bubble was generated periodically with Group I heaters (a)–(f) with width of the slim part of the heater less than or equal to 10 µm, and an oblate vapor blanket was generated periodically with Group II heaters (g)–(k). The fact that the shape of the bubble and boiling pattern depend on the slim part of the heater can be explained as follows: after the incidence of boiling, the water–vapor interface will try to form a spherical bubble within the thin superheated liquid due to the surface tension effect, which is the dominant force at the microscale level. The spherical vapor bubble stops growing near the outer edge of the thin superheated region because of its contact with the cooled

Thermal Bubbles, Table 1 Dimension of various submicron and micron heaters [13]; The length and width are measured at the slim part of the microheater

Heater ID	Length (μm, ±2%)	Width (μm, ±3%)
(a)	0.5	0.5
(b)	1	0.5
(c)	2	1
(d)	10	3
(e)	10	5
(f)	20	10
(g)	30	10
(h)	30	15
(i)	90	30
(j)	150	50
(k)	200	70



Thermal Bubbles, Figure 10 Semi-logarithmic plot of bubble diameter versus time for spherical bubble growth and collapse on submicron heaters and micron-heaters at a pulse width of 1.66 ms [13]

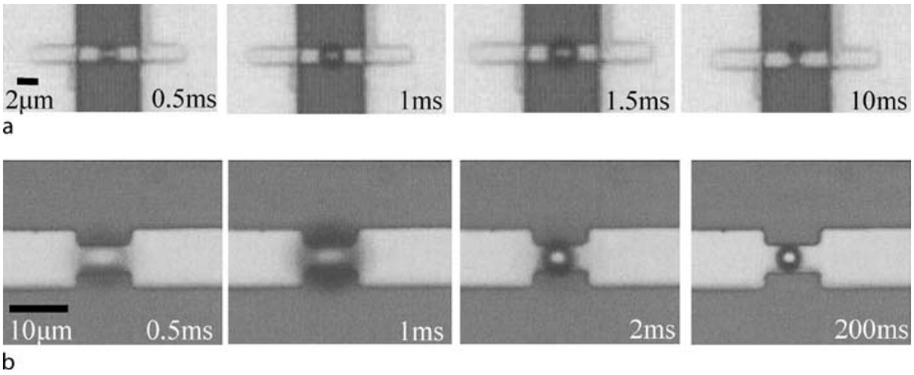


Thermal Bubbles, Figure 9 Map of boiling patterns for various sizes of microheaters [13]

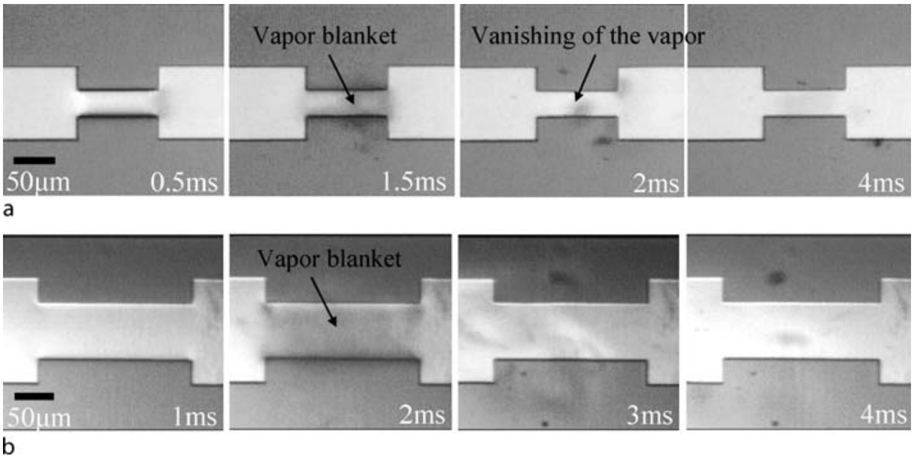
liquid. When the heater has exceeded a certain critical length, the growth of the spherical bubble cannot fit within the thin superheated region, and it grows within the thin superheated region as an elongated bubble on the heater. Because of the larger area of the elongated bubble that is exposed to the outer cooled fluid, the condensation effect is much stronger than the spherical bubble and so it collapses immediately.

Single Spherical Bubble A semi-logarithmic plot of the diameter of spherical bubble as a function of time for the Group I heaters is shown in Fig. 10, which was obtained by using a digital image processing program. The variations in the bubble diameter with time were very similar to each other and a clear bubble growth and collapse process were recorded. In all cases, the spherical bubble growth period was comparable to the width of the heating pulse (1.66 ms). After reaching its maximum size, the bubble began to collapse on the heater surface, and the collapse period, which could last for 10 – 450 ms, was longer than the growth period. The maximum bubble diameter was comparable to the size of the microheater due to the highly localized heating resulting in a superheated zone on the microheater. The bubble lifetime decreased with the heater size due to the shrinking of the superheated zone. Figure 11a shows the growth and collapse of the bubble on a submicron heater having an area of $1 \times 0.5\ \mu m^2$ at a pulse heating power of 1.3 mW and a heat flux of $112.4\ MW/m^2$. Figure 11b shows the growth and collapse of the microbubble on a microheater having an area of $10 \times 5\ \mu m^2$ at a pulse heating power of 38.5 mW and a heat flux of $85.2\ MW/m^2$. Note that in each of these photos, there is a bright circle at the middle of the spherical bubble, indicating a curved spherical vapor–liquid interface.

Film Boiling Oblate vapor blanket or film boiling was found on the surface of the Group II heaters (g)–(k) with the slim part of the heater greater than 10 μm. Figures 12a and 12b show that boiling patterns on the heaters having an area of $150 \times 50\ \mu m^2$ and $200 \times 70\ \mu m^2$, respectively. No single spherical bubble was observed. Instead, an oblate vapor blanket was formed on the heater surface, and it disappeared almost immediately after the pulse heating stopped at 1.66 ms. The light intensity of the vapor layer on the surface of heaters of Group II was fairly uniform, indicating a relatively planar vapor–liquid interface.



Thermal Bubbles, Figure 11 Spherical bubble generated in water under 1.66 ms pulse heating: (**a**) on submicron heater ($1 \times 0.5\ \mu m^2$) at pulse heating power of 1.3 mW and heat flux at 112.4 MW/m^2; (**b**) on a microheater ($10 \times 5\ \mu m^2$) at 38.5 mW at heat flux of 85.2 MW/m^2 [13]



Thermal Bubbles, Figure 12 Oblate vapor blanket on the heater surface (**a**) on a microheater ($90 \times 30\ \mu m^2$) at pulse heating power of 808.2 mW and at a heat flux of 46.3 MW/m^2; (**b**) on a micron heater ($200 \times 70\ \mu m^2$) [13]

Onset of Bubble Nucleation

Effect of Heater Size on Nucleation Temperature and Nucleation Time

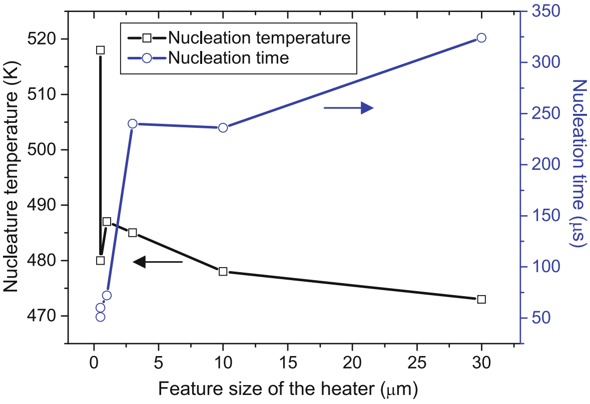
Deng et al. [13] experimentally investigated the effects of the size of the heater on the temperature variations of microheaters at a specific pulse width τ of 1.66 ms. The inflection point and temperature discontinuity point of the temporal variations of the surface temperature of the submicron heaters and microheaters were identified as the respective nucleation temperatures. The nucleation temperature and nucleation time for various heaters are presented in Fig. 13. The horizontal axis of this figure is in terms of the featured size of the heater, L_c, which is defined as the square root of the area of the slim part of the heater, i.e., $L_c = (L \times W)^{1/2}$ with W and L being the width and the length of the microheater, respectively. It is shown that the nucleation temperature increases while the nucleation time decreases as L_c decreases. This is because the rate of temperature increase of the heater decreases with the size of the heater.

Microbubble Growth and Collapse and Nucleation Temperature in DNA Solutions

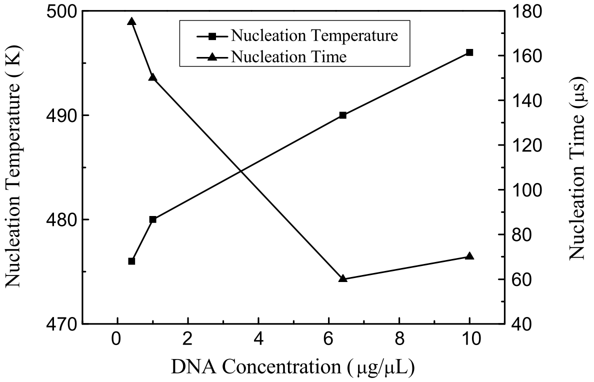
Bubble Growth and Collapse in DNA Solutions

It is known that the viscosity of the single-stranded DNA (ssDNA) solution increases with its concentration [14]. It was found that the overall bubble lifetime in ssDNA solutions decreased distinctly with the increase in the ssDNA concentration [14].

Figure 14 shows the variation of bubble diameter immediately after pulse heating is imposed for the concentrations of 0 µg/µl, 0.1 µg/µl, 1 µg/µl, 6.4 µg/µl, and 10 µg/µl

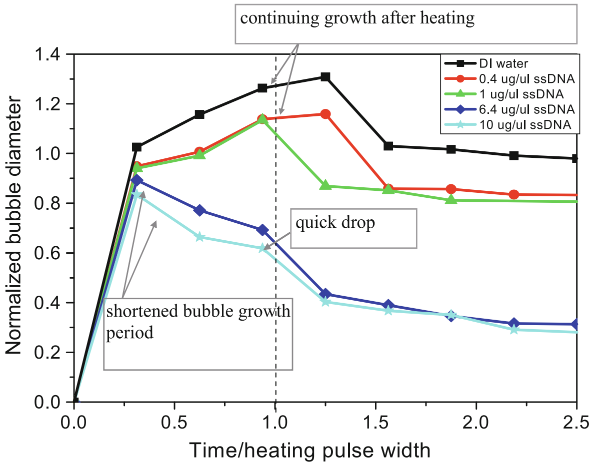


Thermal Bubbles, Figure 13 Effects of heater size on nucleation temperature and nucleation time at $\tau = 1.66$ ms [13]



Thermal Bubbles, Figure 15 Effects of concentration on the nucleation temperature and time [12]

ssDNA solutions, respectively [14]. In this figure, the time is normalized by the heating pulse width (1.66 ms) and the bubble diameter is normalized by the characteristic size of the microheater L_c. It is shown that the maximum bubble diameter decreases with the increase of the ssDNA concentration. For both DI water and 0.4 µg/µl ssDNA solution, the largest bubbles were recorded 2 ms after the start of the heating process, implying that the bubble kept on growing even though the heating pulse stopped at 1.66 ms, due to the inertia effect. For the case of 1 µg/µl, the maximum-size bubble was recorded at 1.5 ms, implying that the bubble stopped growing at almost the end of the heating pulse. For high concentrations of 6.4 µg/µl and 10 µg/µl, however, the largest bubbles were both recorded at 0.5 ms, indicating that the bubble growth process was much shorter than that at moderate concentrations, and the bubble stopped growing even though the heater was still operating. From this graph, it can be concluded that high concentrations of the DNA macromolecules in a solution can effectively retard the bubble growth by increasing the dissipation of the kinetic energy of the bubbles. As a result, both the bubble growth period and the recorded maximum bubble diameter are distinctively reduced at high DNA concentrations. For medium and low concentrations (1 µg/µl and 0.4 µg/µl, respectively), the bubble growth period is comparable to the heating pulse width.



Thermal Bubbles, Figure 14 Variation of microbubble diameter in ssDNA solutions: (**a**) bubble diameter versus time; (**b**) close-up view of bubble initial growth period [11]

Nucleation Temperature and Nucleation Time in DNA Solutions

The effects of DNA concentration on nucleation temperature and nucleation time are presented in Fig. 15. It is shown that the nucleation temperature increases with DNA concentration. This is because higher nucleation work is required for higher DNA concentrations, leading to higher nucleation temperatures. On the other hand, nucleation time decreases with the increases of the DNA concentration. This is because higher power inputs are required for bubble nucleation in higher DNA concentration, resulting in a faster heating rate and therefore a shorter nucleation time.

Future Directions for Research

Although extensive efforts have been focused on fundamental and applied research on microbubble actuators, the demand for high-speed, high-quality printing will be one of the main drivers of the development of the next generation of inkjet printheads using MEMS technology [15]. In

comparison with the other inkjets, such as the piezoelectric type, the bubble actuator-based inkjet has the advantages of a simple fabrication process and high compatibility with the CMOS process. The applications of bubble actuators to microfluidics based biotechnology, such as DNA microarrayer, microcell manipulator/sorter and micro-oligonucleotide synthesizer, are in the early stage of research, and more studies on the behavior of bubble actuators using different biofluids will be needed for design and fabrication of these devices.

Definition

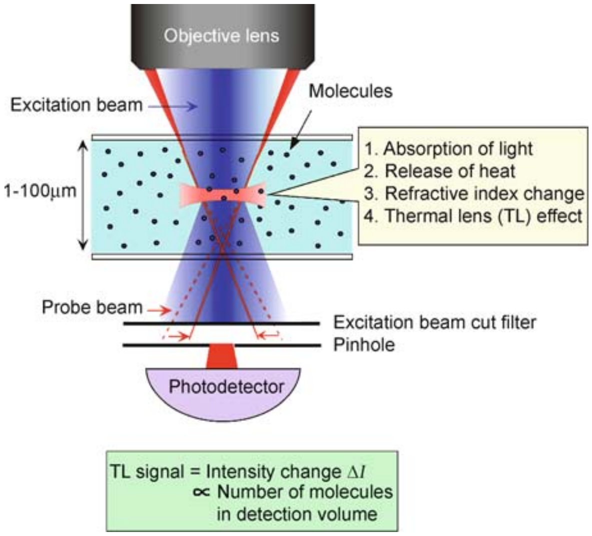
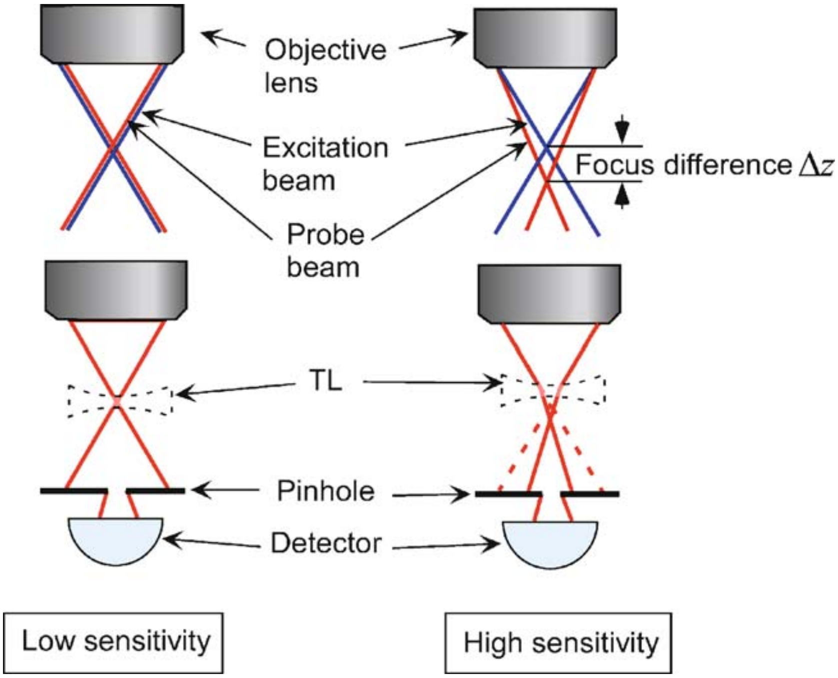
Thermal lensing (TL) is one example of a photothermal phenomenon. When an excitation laser is focused into a non-fluorescent sample in a microchannel, the sample absorbs the excitation laser and releases the light energy as heat following non-radiative relaxation. The heat generation induces a temperature distribution which is similar to a Gaussian profile due to the Gaussian intensity distribution of the excitation laser and heat diffusion. Generally, a temperature increase in a liquid decreases the refractive index, and a refractive index distribution working as a concave lens is formed around the focus. This concave lens is a thermally-induced lens and the phenomenon is known as *thermal lensing*. A thermal lens microscope (TLM) utilizes TL effects for ultrasensitive detection of non-fluorescent molecules in microchannels. The TLM features high sensitivity comparable to that obtained by a fluorescence method and, because there are so many more non-fluorescent molecules, much wider applicability. TLM has been successfully applied to various analytical and chemical synthesis applications on microchips combined with general micro-integration methods by micro-unit operations (MUOs) and continuous flow chemical processing (CFCP).

Overview

The basic principle of TLM is illustrated in Fig. 1 [1]. In a TLM, two laser beams are utilized: an excitation laser beam and a probe laser beam. The wavelength of the former is tuned to the light absorption band of the sample and that of the latter is adjusted to avoid the absorption band. The excitation laser is tightly focused into the sample. The diameter of the beam waist is usually around 1 µm. The sample absorbs the excitation beam, and heat is released to the solvent around the molecule, increasing temperature of the solution. The light absorption is linearly dependent on the light intensity distribution which is a Gaussian distribution, and the resultant temperature distribution is sim-



Thermal Lensing, Detection, Figure 1 Basic principle of TLM



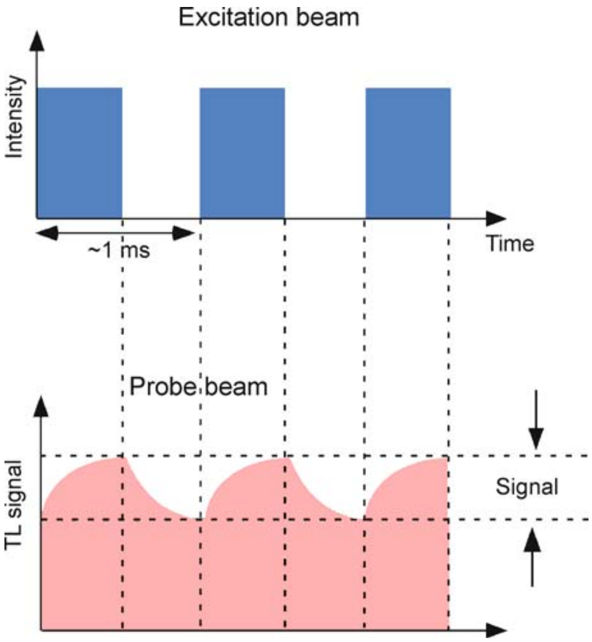
Thermal Lensing, Detection, Figure 2 Illustration of sensitive TL detection by focal length difference Δz: $\Delta z = 0$ (left) and $\Delta z \cong z_C$ (right)

ilar to the intensity distribution. The strength of the lens at thermal equilibrium is expressed as,

$$\frac{1}{f} = \frac{P\varepsilon Cl\,(\mathrm{d}n/\mathrm{d}T)}{\pi J\kappa\omega_0^2} \tag{1}$$

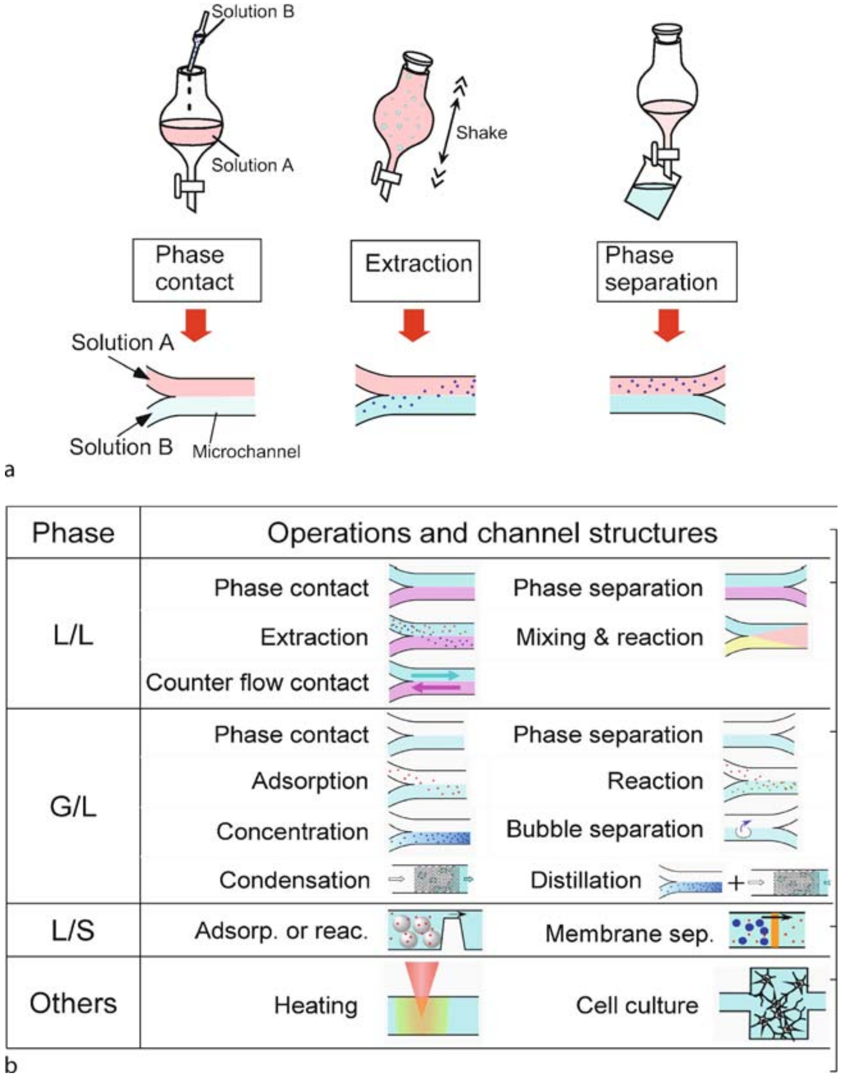
where f is the focal length of the thermal lens near the optical axis, J is the Joule coefficient, κ is the thermal conductivity of the medium (usually solvent in dilute solutions), ω_0 is the radius of the beam waist, P is the power of the excitation beam, ε is the molar absorption coefficient of the sample, C is the concentration of the sample, l is the optical path length of the cell (usually the depth of the cell if the change of the waist ω is ignored) and $\mathrm{d}n/\mathrm{d}T$ is the first derivative of the refractive index, n, of the medium by temperature, T.

For detection of the TL effect, a probe beam is coaxially introduced into the objective lens and focused on the sample. The radius of the spot is also calculated from Eq. (1). When the excitation beam is focused on the sample and the TL effect is induced, the optical path of the probe beam is changed. The change in the optical path is detected by measuring the probe beam intensity through a pinhole. For dilute solutions, the intensity change ΔI is proportional to $1/f$ in Eq. (1) and is defined as a thermal lens signal. The sign of ΔI depends on the TL effect on the probe beam, which is either converging or diverging, and is determined



Thermal Lensing, Detection, Figure 3 Signal recovery by intensity modulation of the excitation beam (upper) and synchronous detection of the same frequency component by a lock-in amplifier (bottom)

by the relative focal positions of the probe and excitation beams. When the focus of the probe beam is closer to the



Thermal Lensing, Detection, Figure 4 Realization of micro-unit operations (MUOs): (**a**) example of solvent extraction and (**b**) MUOs developed for various phases

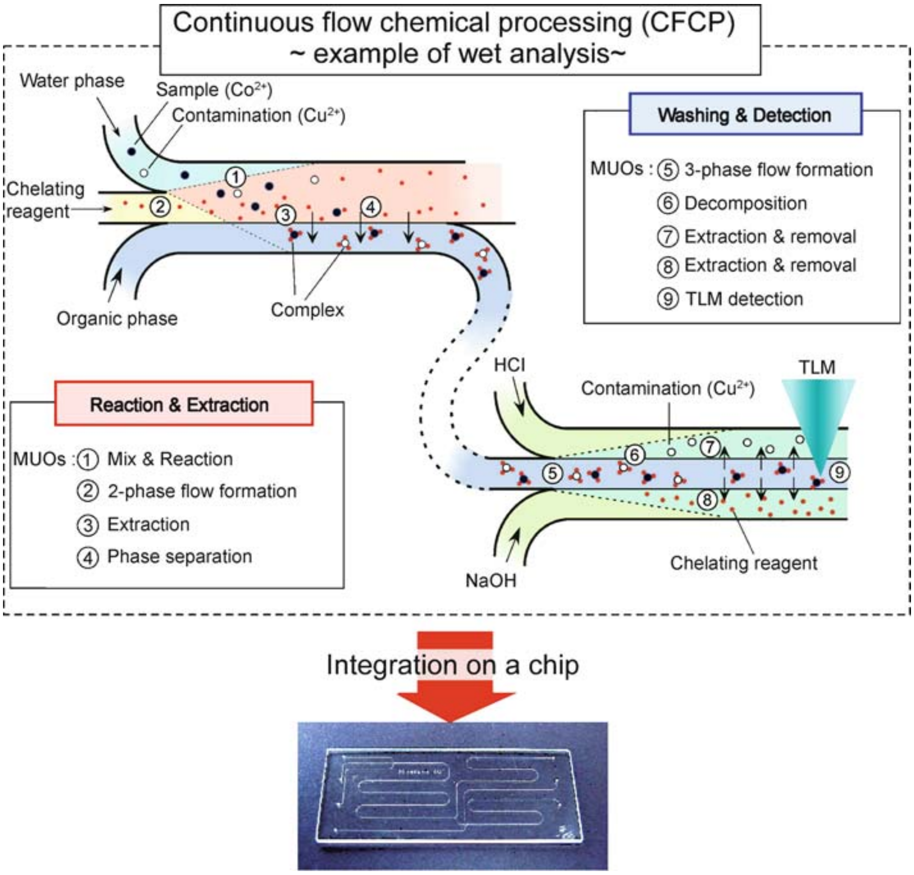
objective lens than that of the excitation beam, the probe beam diverges.

As shown in Eq. (1), the sensitivity of the TL signal depends on chemical and physical properties of the solution. For the chemical properties, the enhancement factor $(\mathrm{d}n/\mathrm{d}T)/\kappa$ is very important. Usually, organic solvents are favorable due to higher $\mathrm{d}n/\mathrm{d}T$ and smaller κ [1]. Water shows the lowest enhancement factor. For example, carbon tetrachloride has an approximately 40 times greater enhancement factor than water.

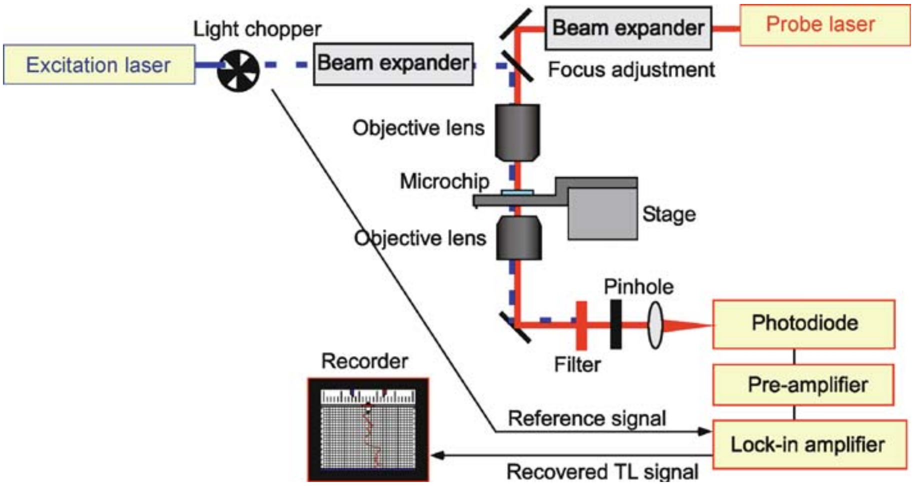
For the physical properties, the enhancement factor $P/\pi\omega_0^2$ is important. Tightly focusing the excitation beam leads to a strong TL effect; however, it also leads to a large divergence of the excitation beam due to light diffraction and the effective length of the TL contributing to the signal decreases. The detection depth should be experimentally determined.

The most important point to realize sensitive TLM is a focal length difference between the excitation beam and probe beam as shown in Fig. 2. When the focal lengths of the two beams are the same, the probe beam is focused at the center of the TL. In this case, the optical path of the probe beam is not changed, and the signal intensity becomes almost zero. An adequate focal length difference Δz is necessary for realizing optimum sensitivity. The optimum Δz is estimated by

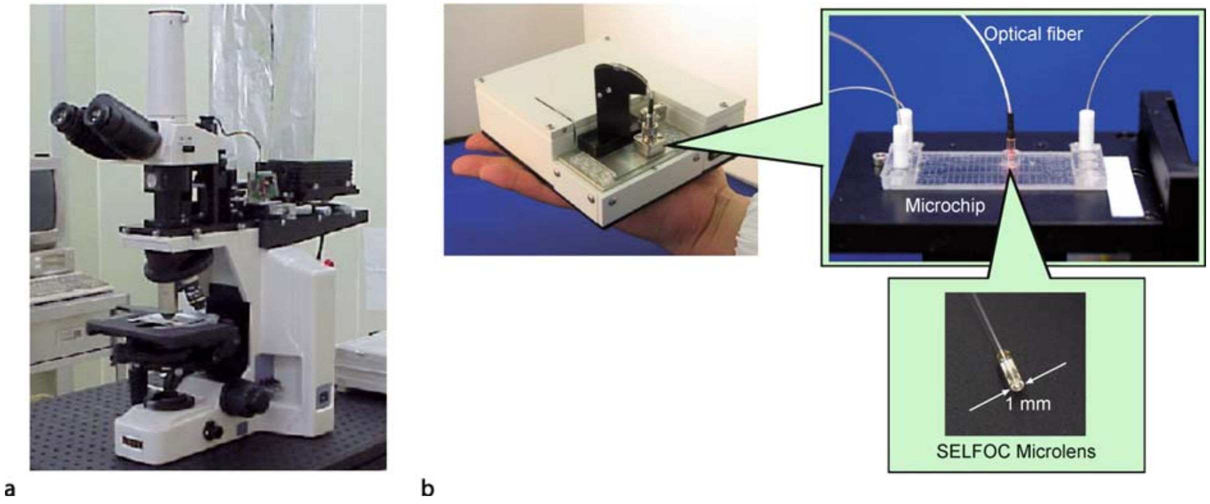
$$\Delta z \cong \sqrt{3} z_{\mathrm{c,pr}} \tag{2}$$



Thermal Lensing, Detection, Figure 5 Concept of continuous flow chemical processing (CFCP) and TLM detection for general micro-integration: an example of wet analysis on a microchip



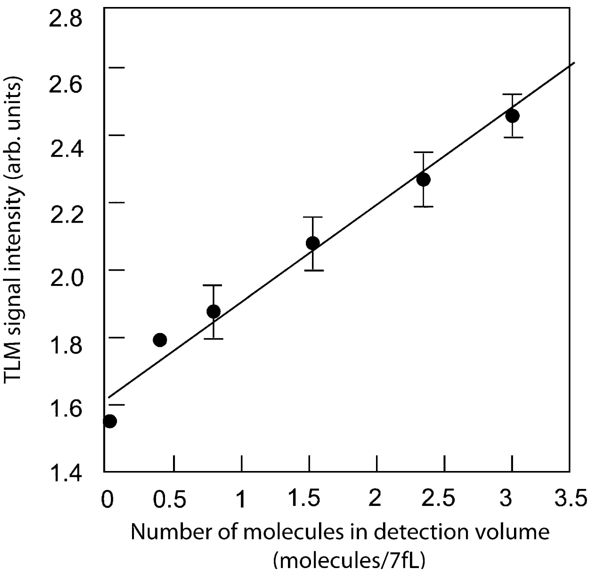
Thermal Lensing, Detection, Figure 6 A typical TLM system



Thermal Lensing, Detection, Figure 7 a) Desktop-sized TLM and b) palmtop-sized TLM

where $z_{c,pr}$ is a confocal distance of the probe beam. However, Eq. (2) assumes that $z_{c,pr}$ is much larger than the TL thickness which is investigated based on Eq. (2). The exact value should be determined by measuring the dependence of the TL intensity onΔz.

Next, the signal processing to recover TL signals from large thermal noises is illustrated because the TL effect is very weak; typically the largest value of ΔT is 10^{-3} degrees and Δn is less than 10^{-7}. The former value is as small as the thermal fluctuation and easily affected by environmental temperature change. In order to recover the true TL signal, the intensity of the excitation beam is modulated at a certain frequency and the synchronous signal of frequency in the probe beam intensity change is detected by a lock-in amplifier. The lock-in amplifier works as an ultra-narrow band pass filter. A typical waveform is illustrated in Fig. 3. Finally, the concept of a general micro-integration method and coupling with the TLM are illustrated. In the 1990's, most microchip-based analytical systems were concerned with genome or protein analysis by electrophoresis with fluorescence detection. However, many other analytical and synthesis applications were expected in general chemistry, organic synthesis, combinatorial chemistry, physical chemistry, and biochemistry that involve complicated chemical processes, organic solvents, neutral species, and non-fluorescent detection. For this purpose, we first realized conventional unit operations on microchips as micro-unit operations (MUOs) utilizing multiphase laminar flow as shown in Fig. 4. These MUOs were connected by continuous flow chemical processing (CFCP) to form a multiphase laminar flow network (Fig. 5), and TLM was utilized for detection of

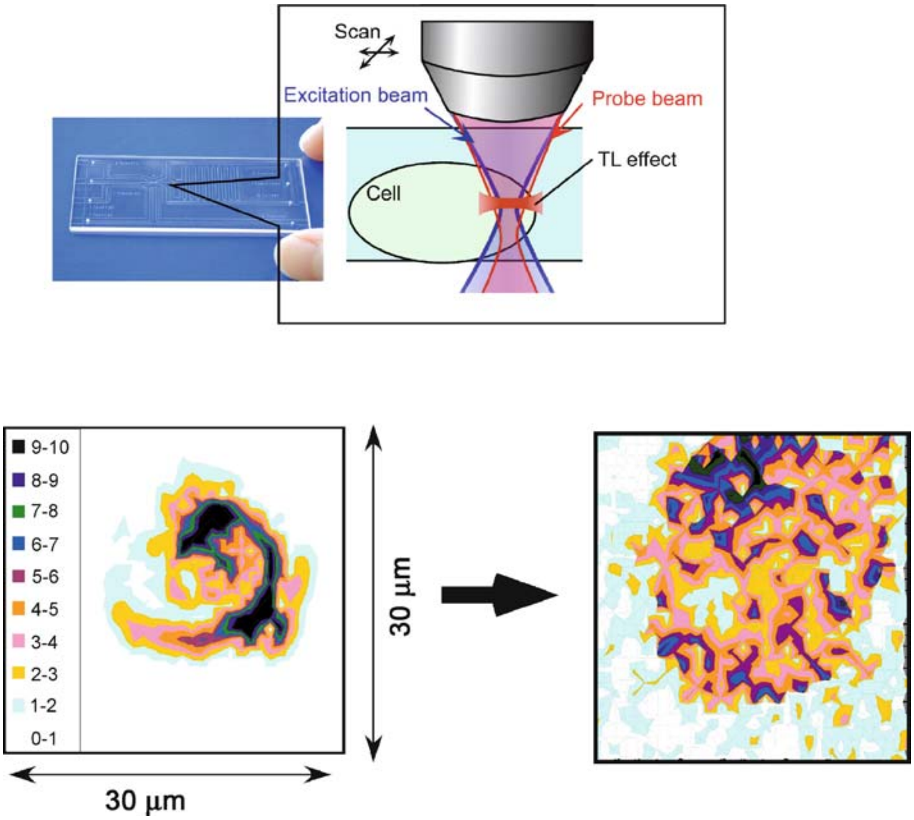


Thermal Lensing, Detection, Figure 8 Performance of TLM for ultrasensitive detection of molecules. The sample was lead(II)-porphyrine complex solution

non-fluorescent molecules. These concepts have opened various analytical and chemical synthesis applications on microchips with wide applicable and sensitive TLM detection.

Basic Methodology

A typical TLM system is illustrated in Fig. 6. The output of the excitation beam is intensity-modulated by a light



Thermal Lensing, Detection, Figure 9 Single cell imaging by scanning TLM. Cytochrome C was directly measured by scanning the laser beams with a 1 µm increment

chopper. The excitation beam is expanded by a beam-expander to adjust the beam size to the size of the input pupil of an objective lens. Then, the excitation beam is introduced into a microscope through a dichroic mirror and a prism. The probe beam is also expanded by a beam-expander. The distance between the two lenses in the beam expander is adjusted to control the divergence of the probe bam and focal length difference Δz. Then, the probe beam is reflected by the dichroic mirror and introduced into the microscope coaxially with the excitation beam. The objective lens of the microscope focuses the excitation and probe beams into a sample on a microchip. The TL effect is induced in the sample, and the probe beam is converged or diverged due to the TL effect depending on the focal position as described in the previous section. The two transmitted beams are collimated by another objective lens and reflected by a mirror and focused by a third lens. The excitation beam is removed by a filter, and only the probe beam is focused onto the pinhole and collected by a photodiode. The photodiode converts the light intensity of the probe beam to an electronic signal which is amplified by a pre-amplifier. Then, the amplified signal is fed into a lock-in amplifier. The lock-in amplifier extracts synchronous signals in the large background, and the amplitude and phase are measured as TL signals. Available wavelengths range from deep-UV to IR regions.

Desktop- and palmtop-sized TLMs are commercially available (Fig. 7) [2]. In the palm-top TLM, laser-diodes are utilized as excitation and probe beams, and these beams are introduced to a microchannel via a light mixer and a single-mode optical fiber. The palm-top TLM can also be integrated into a system. For example, an allergy analysis system with the palmtop-sized TLM has been reported.

Key Research Findings

Realization of TL detection under a microscope allows ultrasensitive detection of non-fluorescence molecules. An example of dye solution detection in a microchannel is illustrated in Fig. 8 [3]. The microchannel was 150 µm wide and 100 µm deep. The solvent used was benzene and the molar absorption coefficient of the porphyrine complex was $3.2 \times 10^4\ \mathrm{M}^{-1}\mathrm{cm}^{-1}$. The expected value was cal-

culated by multiplying the concentration and the detection volume (7 fL). The signal intensity showed good linear dependence on the expected value. The lower limit of detection was estimated to be 0.32 molecules from the conditions of a signal-to-noise ratio (S/N) of 2 and a signal-to-background ratio (S/B) of 0.1 for an averaging time of several seconds. In comparison with spectrophotometry, more than six orders higher sensitivity in the absolute molecular number is achieved. This ultra-high sensitivity with wide applications for non-fluorescent molecules holds the promise of a powerful tool for various microchip-based analytical or chemical synthesis applications.

TLM can also be utilized for imaging by scanning the laser beams. Figure 9 shows the direct imaging of a single neuron cell by measuring Cytochrome C for monitoring an apoptosis process [4]. In situ imaging of a single cell with almost 1 μm spatial resolution was successfully realized [5]. Many other applications such as in situ immunoassay on biological cells or membranes have also been reported [5].

A summary of example TLM applications coupled with MUOs developed and CFCP is made in

Future Directions for Research

In a previous section, just one example of ultrasensitive concentration determination of non-fluorescent molecules was given. However, the area of micro- and nano-fluidics is rapidly expanding and high degrees of functionality are desired for detection methods.

For these purposes, various functional TLMs have already been realized. For example, sensitive chiral recognition by circular-dichroism TLM (CD-TLM) was reported for synthesis and analysis of drugs on microchips [6]. Other reports have described an electrochemical TLM [7], flow sensing TLM, UV TLM [8], and TLM spectrometer [9].

As important functions for science and technology in micro- and nano-fluidics, three functions are highly desired: individual molecule detection as the ultimate sensitivity, fast (real-time) imaging, and femtosecond time-resolved measurement for investigating molecular dynamics in a nano-space.

The design method of these functional TLMs is also important. The TL effect is usually very complex in the micro- and nano-space and its basic science is still an important issue. Development of a theoretical analysis tool which combines fluidics and optics is desired for this purpose.

Thermal capacitive flow sensor

Definition

The thermocapacitive flow sensor is a velocimeter used to measure the rate of fluid flow. In a thermocapacitive flow sensor, there is a heater and sensing capacitor, which has a dielectric material with a temperature-dependent dielectric constant. The heater is located close to the capacitor. If electric power is supplied to the heater, it causes the temperature of the capacitor to rise. The dielectric constant of the capacitor increases with temperature, resulting in an increase in the capacitance. When the fluid flows through the capacitor, the temperature of the capacitor will decrease due to the convective heat transfer from the capacitor to the fluid. Thus the capacitance will also be reduced. Through measuring the capacitive value, the flow velocity can be obtained by a calibration relationship between the flow rate and the capacitance.

Overview

Fluid flow is important not only in almost all engineering fields, but also in micro- and nanofluidic chips. Flow measurements are required to: increase our understanding

of the physicochemical mechanisms of processes; improve the designs of the devices; and enhance the corresponding function of the devices. The measurement of the flow velocity is important in fluid mechanics. There are many conventional advanced velocimetries in fluid mechanics: hot-wire anemometry (HWA), laser Doppler velocimetry (LDV) and particle image velocimetry (PIV) [1]. These methods have been applied in microfluidics to measure the flow velocity in microchannels [2–4]. For microfluidics, there are several other methods to measure flow velocity, these have been reviewed elsewhere [5].

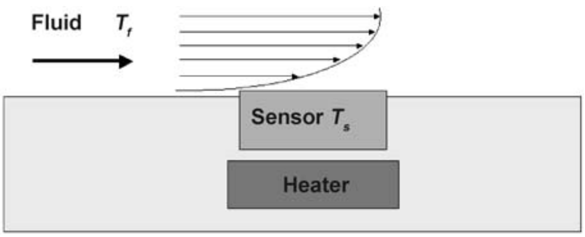
Thermal flow sensors based on convective heat transfer are usually used to measure the flow rate, since a heater can easily be realized by applying electric power to a electric resistor. For instance, HWA, one of the most widely used velocimetries, is a thermal flow sensor.

All thermal flow sensors are based on the convective heat transfer between a flowing fluid and a sensing solid element. Figure 1 shows a simplified case of convective heat transfer which explains the thermal flow sensing principle. A heater heats a solid sensor, which faces the flowing fluid. When power is supplied to the heater, the sensor temperature increases to T_s. As the fluid flows through the solid sensor, there will be a convective heat transfer from the sensor to the fluid. If Q is the heat transfer rate, A_h is the interface area perpendicular to the direction of heat flow between the sensor and the fluid. T_s and T_f are the temperature of the sensor surface and fluid, respectively. The heat transfer can then be described as

$$Q = \mathrm{Nu}\, A_h\, (T_s - T_f) \qquad (1)$$

where Nu $(= \alpha_c L/k_d)$ denotes the Nusselt number, α_c is the convective heat transfer coefficient, L represents the characteristic length for the heat transfer, and k_d is the thermal conductivity of the fluid. Nu normally depends on the flow and material properties and can be described as

$$\mathrm{Nu} = f\nu\, (\mathrm{Re}, \mathrm{Pr}) \ , \qquad (2)$$



Thermocapacitive Flow Sensor, Figure 1 Simplified case of convective heat transfer

from Eq. (1) and Eq. (2):

$$T_s = \frac{Q}{f\nu\,(\mathrm{Re}, \mathrm{Pr})\, A_h} + T_f = \frac{Q}{f\nu\,(uL/\mu, \mathrm{Pr})\, A_h} + T_f \qquad (3)$$

where Re $(= uL/\nu)$ is the Reynolds number and Pr $(= c_p\mu/k_c)$ denotes the Prandtl number. u, ν, μ, c_p, and k_c are the flow velocity, kinematic viscosity, dynamic viscosity, specific heat, and thermal conductivity of the fluid, respectively [6]. The relationship between Nu and u depends generally on flow (e. g., laminar, turbulent), the geometry of the sensor, the position and the orientation of the sensor to the flow. Nu(Re, Pr) does not have a universal formula. When constant power is applied to the heater, it will cause the temperature T_s to rise. However, when the fluid passes through the sensor, the convective flow will reduce T_s. The higher the flow velocity, the lower the value of T_s. If the fluid temperature, composition, and pressure are constant, the only variable that affects the convective heat transfer or T_s is the flow velocity u. The heater can be an electric resistant. Thus, the flow velocity can be determined by measuring the temperature T_s directly or other variables that are, in turn, related to T_s.

A thermal flow sensor typically consists of a heater and one or more temperature sensors. The heater can operate at either constant heating power or at a constant heating temperature. In thermal microflow sensors, the flow rate is evaluated by measuring the heating power, the temperature of the heater or fluid, and the time of flight of a heat pulse [7].

There are three types of thermal flow sensors that combine the evaluation methods and heater modes: hot-wire (hot-film), calorimetric, and time-of-flight.

- Hot-wire (hot-film) sensors measure the effect of the flowing fluid on a hot body. At a constant heat power, the forced convection causes a decrease in the temperature of the heater.
- Calorimetric sensors measure the asymmetry of a temperature profile round the heater, which is modulated by the fluid flow.
- Time-of-flight type sensors measure the time that it takes for a heat pulse to move a known distance.

In principle, any temperature-dependent property of a solid-state material could be used for temperature measurement. Each of the sensor types can be further categorized, according to their thermal sensing principle as: thermoresistive, thermoelectronic, pyroelectic, thermophilic elements, microresonator structures, or thermocapacitive [7].

In this essay, we focus on the thermocapacitive flow sensor. The advantages of the thermocapacitive flow

sensor are: its low cost arising from batch fabrication; on-chip electronic signal-conditioning circuitry for enhanced performance; low power consumption; low noise due to the metal oxide semiconductor (MOS); and reduced dimensions. Its disadvantages include the fact that it has difficulty measuring velocity distribution in flow fields due to the relatively poor spatial resolution. There are also difficulties with using the thermocapacitive flow sensor in liquids, due to electrical insulation, and in electrokinetic flows, as it could interfere with the flow.

Basic Methodology

The thermocapacitive flow sensor is based on a dielectric material with a temperature-dependent dielectric constant. The sensing module is a capacitor. If the electric power is supplied to a heater that is close to the capacitor, the temperature of the capacitor will increase, causing an increase in the dielectric constant, and thus, an increase in the capacitance of the capacitor. When a fluid flows through the capacitor and if its temperature is lower than that of the capacitor, the temperature of the capacitor will decreases due to the convective heat transfer between the fluid and the capacitor. The temperature of the dielectric material of the capacitor will decrease, resulting in a decrease in the capacity. The higher the flow velocity, the lower the capacity. Therefore there is a relationship between the flow velocity and the capacitance. Like the HWA, with a calibration relationship between the flow velocity and the capacitance, the flow velocity can be calculated by measuring the capacity of the capacitor.

The measurement of flow rate is one of main subjects in experimental fluid mechanics. However, the thermocapacitive flow sensor may have electronic and semiconductor components, such as a capacitor, an n-channel MOS transistor, an oscillation circuit, and microfabrication. Therefore, the thermocapacitive flow sensor is a multidisciplinary tool and some of its electronic and semiconductor components need to be explained.

Components

Capacitor

A parallel-plate capacitor consists of two closely spaced conductive plates. A nonconductive material is termed a dielectric. When the space between the two plates is occupied by a dielectric material, the capacitance is increased by a factor κ that is characteristic of the dielectric and is known as the dielectric constant or dielectric coefficient [8].

$$C = \kappa C_0 = \kappa \left(\frac{A}{d} \right) \tag{4}$$

where C_0 is the original capacitance, A represents the area of the plates, and d is the distance between the surfaces of the two plates. The capacitance C depends on the dielectric constant and the geometrical configuration, but is independent of the voltage on it. Since the dielectric constant κ is dependent on the temperature and frequency, the capacitance C is also a function of the temperature.

N-Channel MOS

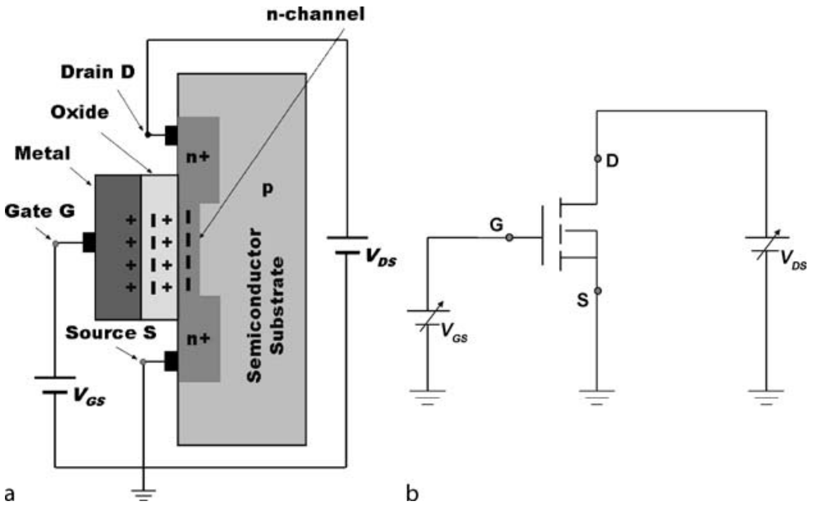
Figure 2 illustrates the MOS structure that consists of a semiconductor substrate layer, a middle oxide layer and a top metal layer which acts as the control gate. Most transistors are MOS field-effect transistors (MOSFETs) and the metal gate has mostly been replaced by a polysilicon gate. Although the term insulated gate field effect transistor (IGFET) is sometimes preferred, we will continue to use the term MOS, because it is used in the relevant publication [9]. There are three terminals: D (drain), S (source), and G (gate) in a MOSFET.

The MOS is a voltage sensitive device and operates as the positive gate voltage. This positive potential on the gate causes a polarization of the charges within the oxide insulator as illustrated in Fig. 2. The positive charges (holes) are aligned along the inner surface of the oxide. Consequently, these positive charges attract the negative charges (electrons) from the p-substrate to the area of the oxide. When more electrons are attracted into the n-channel region under the gate oxide than there are holes in the n-channel, that is when the gate voltage is higher than the threshold voltage, the n-channel is created to bridge the two n^+ regions. n^+ regions are so-called in order to emphasize the very large n impurity. If a positive drain voltage is now applied between the D and S terminals, n-channel electrons provide a conducting path between the two n^+ sections and current flows between the source and drain.

A floating gate MOS has one more layer than a MOS. This layer is called the floating gate. It is situated between the control gate and the semiconductor substrate and is surrounded by the oxide insulator (see Fig. 3).

The Sensing Capacitor Module

The sensing module is a capacitor, which has a dielectric layer, whose dielectric constant increases with temperature. In practice the capacitor module can be fabricated

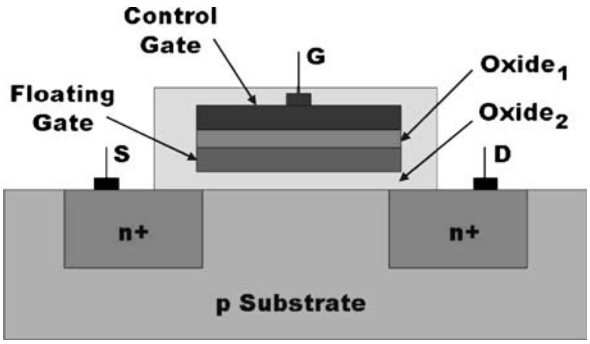


Thermocapacitive Flow Sensor, Figure 2 n-channel MOS structure and wiring. (**a**) n-channel MOS structure; (**b**) diagram showing how the MOS is wired to obtain the current between source and drain

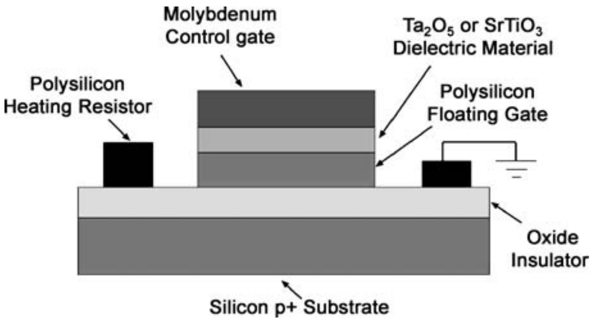
using a MOS-compatible process combined with ethylenediamine pyrocathechol (EDP) groove etching [9, 10] as shown in Fig. 4. The capacitor module consists of multilayers, such as molybdenum for the control gate, a dielectric material Ta_2O_5 [9] or $SrTiO_3$ [10], a polysilicon floating gate, and an oxide insulator. A heating resistor, that can be an electrical resistance, is also included in this module.

Measuring Variables

The sensor operation is based on convective cooling by fluid flow of the sensing capacitor, which is initially heated by a polysilicon microheater which is in close proximity to it. Two variables have been used to measure the flow rate: voltage [9] and oscillation frequency [10].



Thermocapacitive Flow Sensor, Figure 3 Structure of a floating gate MOS



Thermocapacitive Flow Sensor, Figure 4 Sensing capacitor module

MOS Amplified Voltage Output

A schematic of the sensor circuit is shown in Fig. 5 [9]. The sensing capacitor module with a dielectric material (such as Ta_2O_5 or $SrTiO_3$) and a n-channel MOS transistor M_1 together constitute a floating-gate MOS transistor. C is the coupling capacitor between the control gate and the floating gate. For purposes of thermal isolation, the capacitor C and the heating resistor can be located on a cantilever structure, which can be fabricated by bulk micromachining in EDP. The rest of the floating gate MOS was located on the substrate area to avoid heat transfer from the heating element.

The sensor works in the current saturation region where the drain current I_d is nearly independent of the drain–source voltage V_{DS}. The saturation drain current of the floating gate MOS transistor is governed by the follow-

ing equation in simplified form [9]:

$$I_{\mathrm{d}}=\frac{K}{2}\left(\frac{C}{C_{\mathrm{T}}}V_i+W_{\mathrm{B}}V_{\mathrm{B}}-W_{\mathrm{s}}V_{\mathrm{s}}-W_{\mathrm{T}}V_{\mathrm{th}}\right)^2 \quad (5a)$$

Using Eq. (4),

$$I_{\mathrm{d}}=\frac{K}{2}\left(\frac{\kappa C_0}{C_{\mathrm{T}}}V_i+W_{\mathrm{B}}V_{\mathrm{B}}-W_{\mathrm{s}}V_{\mathrm{s}}-W_{\mathrm{T}}V_{\mathrm{th}}\right)^2 \quad (5b)$$

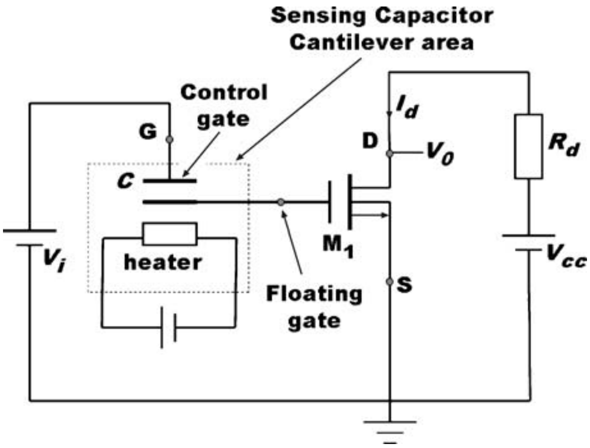
where I_{d} is the drain current, W_{B}, W_{s}, and W_{T} are the coupling ratios which relate to the input voltage V_i, substrate potential V_{B}, source potential V_{s} and threshold voltage V_{th}, respectively. C_{T} is the total capacitance associated with the floating-gate including C. K is the transistor transconductance which relates an output quantity (drain current) to an input quantity (gate–source voltage).

By differentiating I_{d} with respect to κ, where the coupling ratios are a function of C directly, we obtain the expression

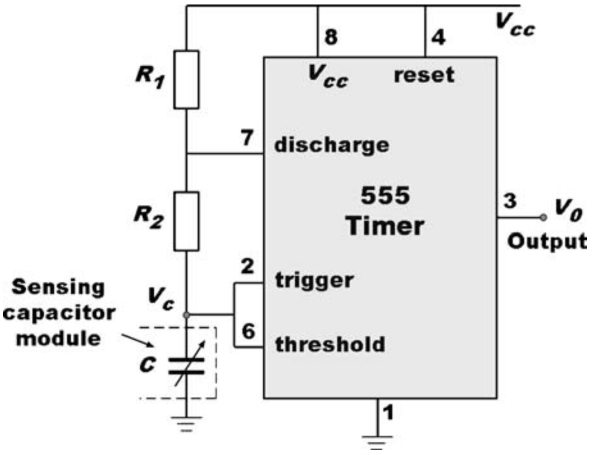
$$\frac{\mathrm{d}I_{\mathrm{d}}}{\mathrm{d}\kappa}=\frac{2I_{\mathrm{d}}C_0}{C_{\mathrm{T}}}\left(\sqrt{\frac{I_{\mathrm{d}}^*}{I_{\mathrm{d}}}}-1\right), \quad (6)$$

$$V_0=V_{\mathrm{cc}}-R_{\mathrm{d}}I_{\mathrm{d}} \quad (7)$$

where I_{d}^* is the drain current in the MOS transistor if the control gate voltage V_i is applied directly in the floating gate and V_0 is the output voltage. Since there is a voltage drop on the capacitor, the control gate voltage is higher than the floating gate voltage. Therefore I_{d}^* is larger than I_{d} and $\mathrm{d}I_{\mathrm{d}}/\mathrm{d}\kappa$ is positive. As a result, I_{d} increases with the dielectric constant κ.



Thermocapacitive Flow Sensor, Figure 5 Circuit schematic of flow sensor measuring capacitor voltage



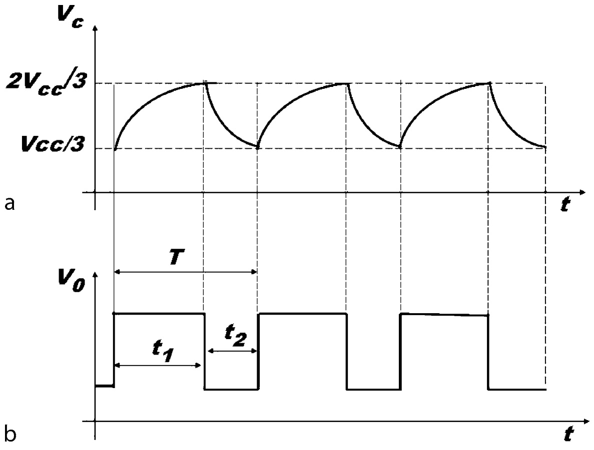
Thermocapacitive Flow Sensor, Figure 6 Circuit of oscillator 555 timer IC chip coupled with sensing capacitor

When power is applied to the heater, the rise in temperature causes the dielectric constant κ in the capacitor to increase, then the drain current increases. When fluid flows through the capacitor convective cooling reduces the temperature, causing κ to decrease, so that the drain current decreases. Therefore the change in the drain current or the output voltage is a measurement of the velocity of the fluid flow.

Frequency Modulated Output

When the sensing capacitor is externally connected to a 555 timer IC chip to form an oscillation circuit as shown in Fig. 6, the oscillation frequency can be used to measure the flow velocity [10]. Here, both inputs of trigger and threshold in 555 timer are connected together. The response of the output voltage V_0 to the input voltage V_{c} on the capacitor is illustrated in Fig. 7.

The lower threshold (V_{TL}) and the upper threshold (V_{TH}) of the 555 timer are internally set at $V_{\mathrm{cc}}/3$ and $2V_{\mathrm{cc}}/3$, respectively. When power is first applied to the circuit, there is no charge in the sensing capacitor and the output V_0 is set high to V_{cc}, since the capacitor voltage V_{c} is below the lower threshold. The sensing capacitor then starts charging through resistors R_1 and R_2 until V_{TH} is reached, which causes the timer to reset and the output V_0 to reduce to a low level. This turns on the internal discharge transistor, which discharges the sensing capacitor through R_2. When V_{c} reaches V_{TL}, the 555 timer output goes high again and the discharge transistor is turned off. The operation is now cyclic, with the sensing capacitor voltage V_{c} oscillating between $V_{\mathrm{cc}}/3$ and $2V_{\mathrm{cc}}/3$.



Thermocapacitive Flow Sensor, Figure 7 Response of output voltage V_0 to sensing capacitor voltage V_C. (**a**) Sensing capacitor voltage V_C as input; (**b**) output voltage V_0 from 555 timer

The time interval for charging the capacitor is [10]

$$t_1 = 0.693\,(R_1 + R_2)\,C\,. \tag{8}$$

The time interval for discharging the capacitor is

$$t_2 = 0.693 R_2 C\,. \tag{9}$$

The total period of the oscillation is

$$\begin{aligned} T = t_1 + t_2 &= 0.693\,(R_1 + 2R_2)\,C \\ &= 0.693\kappa\,(R_1 + 2R_2)\,C_0 \end{aligned} \tag{10}$$

and the oscillation frequency is

$$f = \frac{1}{0.693\kappa\,(R_1 + 2R_2)\,C_0}\,. \tag{11}$$

Clearly, the period of oscillation T is proportional to the dielectric constant κ. Because of the positive temperature coefficient of the dielectric constant, there is a proportional increase in the oscillation period, due to the increase in the temperature of the capacitor, when power is applied to the heater. With fluid flowing, the convective cooling of the sensing capacitor surface would reduce its dielectric constant κ again and cause the period to decrease. Hence, the change in the oscillation period or frequency is a measurement of the fluid flow velocity.

Fabrication

The function of the thermocapacitive flow sensor strongly depends on the sensing material and the quality of its fabrication. Two dielectric materials have so far been used for the sensing capacitor: Ta_2O_5 and $SrTiO_3$. The more sensitive the dielectric constant to the temperature, the higher the sensitivity of the sensor for measuring the flow rate. The dielectric constant temperature coefficients of Ta_2O_5 and $SrTiO_3$ are 375 ppm/°C and 2000 ppm/°C, respectively [9, 10]. Therefore the latter is more temperature-sensitive than the former.

The microcapacitor module can be fabricated using microfabrication technology. The MOS process and a slightly modified MOS process followed by the groove-etching technique in EDP have been applied for the microcapacitor module [9, 10]. In order to increase the sensitivity of the sensor, the leakage current, which is the current flowing through the capacitor when a DC voltage is applied to the capacitor, should be kept as low as possible. The leakage current depends on the fabrication process. For instance, when oxygen is used as the sputtering gas for the deposition of the dielectric layer during the fabrication, the leakage current is more than four orders smaller than that when argon is used [10]. The leakage current can be at least six orders smaller than the sensing capacitor charging and discharging current.

If the capacitor module (the capacitor and heater) is thermally isolated from the rest of the active device, the sensitivity can be increased. If the module is built on a cantilever, the thermal isolation can be enhanced. The thermal isolation of the heater element from the rest of the active device can be tested by measuring the MOS transistor current–voltage characteristics and the threshold voltage, with and without power to the heater element. The smaller the difference, the better the thermal isolation.

Key Research Findings

Since the capacitance of the capacitor depends on the dielectric constant, which in turn is related to temperature, Fig. 8 shows the relationship between the normalized capacitance and the temperature for the sensing capacitor, where the capacitance increases with the temperature due to the heating from the heater.

Although capacitance can be used as a measurable variable for flow velocity measurement, in practice, voltage is easier to measure. With the MOS, the voltage signal can be amplified to increase the sensitivity. The relation between the voltage and the flow velocity is shown in Fig. 9. The voltage increases with the flow velocity, since the higher the velocity, the lower the dielectric constant of the capacitor. Since the current I_d decreases with the reduction of the dielectric constant in Eq. (3), the output voltage, based on Eq. (4), will increase.

For the frequency modulated output, the relationship between the oscillating frequency from the timer and flow

Thermocapacitive Flow Sensor, Figure 9 Relationship between output voltage and gas flow velocity for heater power at 45 mW and 57 mW, respectively. Reproduced from IEEE Electron Device Letters with permission of IEEE

velocity is shown in Fig. 10. The frequency increases with the flow velocity, due to the decrease in the capacitance with the reduction in temperature. At low velocity, the frequency increases linearly with the flow velocity and saturates at a relatively high flow velocity, as shown in Fig. 10. This trend is consistent with theoretical modeling [11], whose result is also shown in Fig. 10.

Figures 9 and 10 show that the sensitivity of the thermocapacitive flow sensor decreases as the flow velocity increases, similar to the case in the HWA and Laser-Induced Fluorescence Photobleaching Anemometer [12]. However, the sensitivity of the thermocapacitive flow sensor increases with heating power, as the higher power will cause a higher temperature difference between the capacitor and fluid, and the change in the flow velocity will cause a larger variation in the temperature, which will cause a larger signal. The sensitivity can be increased by using a large dielectric constant temperature coefficient and a small capacitor.

The response time, which is inversely proportional to the oscillation frequency, determines how fast a sensor can measure the flow velocity, or the frequency band. The higher the heating power, the larger the response time. This is because the higher heating power will generate a larger capacitance, which in turn, will increase the response time. Such a relationship is shown in Fig. 11, where the frequency decreases as the heater power increases.

In practice, a calibration between flow velocity and measuring variables is required before measuring an unknown flow velocity. When calibrating, the fluid temperature,

composition, and density should be the same as those to be measured and the fluids are expected to be incompressible.

Future Directions for Research

To date, the thermocapacitive flow sensor has only been demonstrated in the semiconductor field for measuring the gas flow rate. Many microfluidic chips and most BioMEMS chips work with a liquid medium. Possible future work includes applications of the thermocapasitive flow sensor in a liquid medium, where electrical insulation would be required.

Definition

The dependence of surface tension on temperature can lead to the existence of a surface stress imbalance when a liquid interface is subject to variations in temperature. These stresses then lead to fluid motion along the interface. In the low Reynolds number situations typical of microfluidics, this motion along the interface rapidly leads to motion in the bulk of the fluid.

Thermocapillarity, Table 1 Surface tension of water from freezing to boiling

Temperature (°C)	Surface tension (mN m^{-1})

50	68.0
60	66.2
70	64.5
80	62.7
90	60.8
100	58.9

Chemical and Physical Principles

The surface tension between a liquid and another immiscible fluid (liquid or gas) accounts for the free energy associated with the creation of a free surface. It has units of energy per unit area, usually taken as $\mathrm{mJ/cm^2}$. The units can also be expressed as a force per unit length, in $\mathrm{mN/m}$, which accounts for the notion that surface tension is indeed a tension that pulls in the direction tangential to the surface.

Statistical mechanics considerations predict that the surface tension (γ) displays a linear dependence on temperature (T),

$$\frac{\mathrm{d}\gamma}{\mathrm{d}T} = \gamma T < 0\,, \qquad (1)$$

where T is a constant, usually negative. Table 1, adapted from [1], provides the values of the surface tension γ for a water–air interface as a function of temperature. This table shows that the surface tension has a linear evolution with temperature, starting at a finite value and ending at a lower but also finite value. Note that the drop of surface tension to zero at the critical point of boiling corresponds to a discontinuity in the value of γ.

Table 2 is adapted from [2] and provides the values of γ and γT for some commonly used liquids in microfluidics.

Thermocapillary Convection: The Bénard–Marangoni Problem

Consider now a liquid layer with a free surface. If this layer is submitted to local variations of temperature, it follows that the surface tension will also vary which will lead in turn to an imbalance in the surface tension. This uneven pulling on the interface can be expressed as a production of surface stresses and may be written as

$$\sigma = \gamma T \nabla_{\parallel} T\,, \qquad (2)$$

Thermocapillarity, Table 2 Values of surface tension, at a temperature $T = 20\ °\mathrm{C}$, and its dependence on temperature for some commonly used liquids in microfluidics

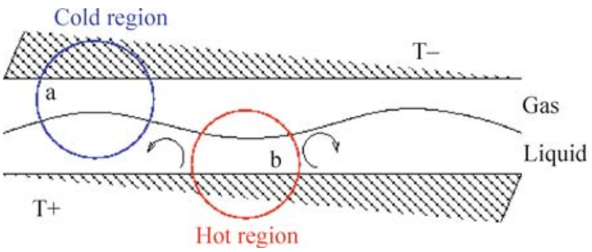
Liquid	Surface tension γ ($\mathrm{mN\,m^{-1}}$)	γT ($\mathrm{mN\,m^{-1}K^{-1}}$)
Water	72.88	– 0.138
Ethanol	22.75	– 0.086
n-Octane	21.80	– 0.10
Benzene	28.88	– 0.13
Perfluoromethyl cyclohexane (C_7F_{14})	15.70	– 0.10

where σ is the local surface stress and $\nabla_{\parallel}$ denotes the gradient along the interface. This surface stress must be compensated by a flow from the region with low surface tension to the region with high surface tension. Since motion along the interface must be accompanied by motion in the bulk in order to conserve the fluid volume, the thermocapillary phenomenon leads to convective motion in the bulk of the heated fluid.

The early experiments by Bénard (1900), which have been reproduced many times since [3], beautifully demonstrate the presence of thermocapillary flow. The setup consists of a cell which is partially filled with a thin layer of liquid and submitted to a temperature gradient perpendicular to the liquid–air interface, as shown in Fig. 1. If we imagine that the layer of liquid has a small initial undulation, it is reasonable to think that the region close to the upper plate (region (a)) is cooler than the region which is close to the lower plate (region (b)). This leads to a decrease in the surface tension of region (b) compared to region (a), which in turn leads to a flow along the surface from (b) to (a). By conservation of mass, this surface flow must lead to recirculation rolls in the bulk, as seen by the arrows in Fig. 1.

Two scaling laws about thermocapillarity are worth noting. First, it should be noted that the numerical values of γT are relatively small and lead to modest changes in surface tension for large variations in temperature. For this reason, thermocapillary effects are often masked in large-scale systems by bulk phenomena, with the notable exception of microgravity situations. One can show for instance that thermocapillary (Bénard–Marangoni) convection is the dominant convection mechanism only for liquid layers shallower than a few millimeters. For thicker layers of liquid, buoyancy effects grow rapidly and dominate the convective motion.

This corresponds to the often-cited notion of surface phenomena becoming dominant over bulk phenomena at small scales. It may be stated more generally by dimensional arguments: the surface area decreases as the square



Thermocapillarity, Figure 1 Bénard–Marangoni experiment, demonstrating flow generated on the surface and in the bulk of a thin layer of liquid

of the typical length scale L, while the volume decreases as L^3. As the scale L of the problem decreases, this implies that the bulk phenomena will decrease faster than the surface phenomena and be dominated by them.

The second scaling law concerns the magnitude of the surface stresses. Note that the stresses caused by the variations in temperature (Eq. (2)) do not depend on the value of the temperature but rather on its spatial gradient. This means that the stresses σ may be strong even for modest changes in temperature, if the scale over which they vary is small enough. Microfluidic scales therefore favor surface stresses due to the variations in temperature.

The above two scaling laws both imply that thermocapillary effects may become a dominant driving mechanism for microfluidics. They have led researchers to explore using thermocapillarity to manipulate fluids in microfluidic situations.

The Solutal Marangoni Effect

Surface tension variations can also be produced by adding surfactants on the interface. These surface active materials (e. g. soap) typically consist of a hydrophilic head group and a hydrophobic tail. Therefore, the presence of surfactants in solution is energetically unfavorable and one gains in free energy if the molecules align along the free surface, which is the equilibrium situation. The creation of a layer of surfactant molecules on the interface then lowers the surface tension of the system.

In transient situations, e. g. in the presence of an external flow or during the formation of droplets, the surface density of the surfactant molecules may be inhomogeneous, which again leads to an imbalance in surface tension, similarly to the thermal case. However, in contrast with the thermal case, the relationship between surface tension and surfactant surface concentration (Γ) is highly nonlinear. A classical model for this dependence states that

$$\gamma = \gamma_0 + RT\Gamma_\infty \ln\left(1 - \frac{\Gamma}{\Gamma_\infty}\right) , \quad (3)$$

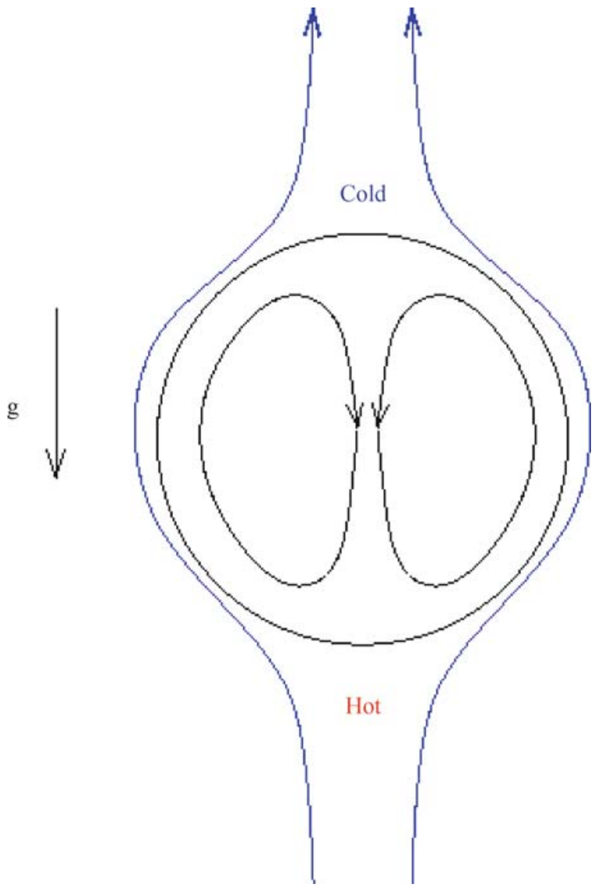
which predicts a steep decrease in surface tension as the surface concentration approaches a finite value, Γ_∞. The value of Γ_∞ is determined by the finite space occupied by the surfactant molecules, which sets an upper bound on the surface concentration. See the entry on ▶ Marangoni Convection for a more detailed discussion of this topic.

Key Research Findings

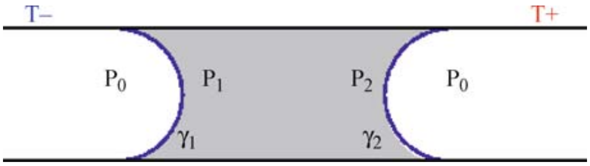
Microfluidic applications of thermocapillarity have centered around the use of temperature gradients to manipulate small quantities of fluid. Young et al. [4], in a pioneering use of thermocapillarity, applied a vertical downward temperature gradient to stabilize the position of a gas bubble against buoyancy. In their experiment [4], the air bubble was subjected to differential heating between its upper and lower sides, as shown in Fig. 2. The flow along the surface, from the hot to the cool side, induces a flow of the external fluid around the bubble in the same direction. The bubble, in reaction to this flow, feels a force which pushes it in the opposite direction. It is as if the bubble were swimming up the temperature gradient.

Experimentally, Young et al. [4] showed that air bubbles a few tens of microns in size could thus be suspended in water between the two cylinders of a machinist's micrometer. The maximum force produced, calculated by balancing the buoyancy force, was of the order of 1 µN.

When gravity can be neglected, which is often the case in microfluidics, the main question that has interested researchers has been that of the velocity of propagation of a drop or a fluid layer for a given temperature gra-



Thermocapillarity, Figure 2 Thermocapillary flow induced by a vertical temperature gradient has been shown to counter the bubble rise due to gravity



Thermocapillarity, Figure 3 A plug of wetting liquid subjected to a temperature gradient, will experience a preasure gradient pushing it towards the hot side

dient. This velocity is given by a balance between the Marangoni stresses and the viscosity. Two categories of such flows can be distinguished. First, when the fluid is in direct contact with a solid substrate, the contact angle between the wall and the substrate imposes a local pressure drop across the interface, through the Young–Laplace law. Therefore the motion of the fluid is associated with a change in the contact angle as well as the change in surface tension. Second, when the fluid is not in contact with the solid, the change in surface tension is associated with a flow of the external fluid, which in turn imposes surface stresses on the drop, as in the experiments of Young et al. [4].

Fluid in Contact with a Solid Substrate

When the drop is in contact with a solid wall, the simplest case is a liquid plug inside a microchannel, shown schematically in Fig. 2. In this figure, we consider a two-dimensional plug of wetting fluid inside a tube. The pressure outside the plug is assumed to be equilibrated at P_0. Inside the plug, there is a pressure jump due to the Young–Laplace pressure, which states that the pressure P_1 is lower than P_0 by an amount γ_1/R where the radius of curvature R may be considered equal to half of the channel size for a wetting fluid. By the same token, the pressure P_2 may be written as $P_0 - \gamma_2/R$. Since the interface at 1 is considered to be cooler than that at 2 and the surface tension drops with increasing temperature, we find that $P_1 > P_2$ and therefore the plug travels towards the hot side.

This first-order analysis accounts for the direction of travel in the channel but does not yield the speed of propagation. The latter is given by a balance between the surface tension deficit and the viscous effects, both in the bulk and at the advancing and receding interfaces. Furthermore, a complete treatment of the problem must also account for the recirculation inside the drop which acts to transport heat from the hot to the cold sides. However, Sammarco and Burns [5] have found experimentally that plug propagation velocities scale linearly with the applied temperature drop for a variety of liquids.

In the case of an open substrate, meaning that only one wall is in contact with the fluid, the initial observation is that a semi-infinite film of liquid subject to a temperature gradient will spread towards the cooler side of the substrate. This can be understood by referring back to Fig. 1 and noting that fluid is pulled towards the cool region, since the surface tension is higher there. A lubrication analysis yields a speed that is proportional to the thermocapillary stress (σ) and to the layer height (h), and inversely proportional to the fluid viscosity (μ).

However, it should be noted that the motion of the film is also associated with a change in its height and the formation of a rim around the advancing interface. This rim was shown to become unstable and to lead to the formation of a fingering pattern with a wavelength (λ) which scales as $h(3\mathrm{Ca})^{1/3}$, where (h) is the film thickness and $\mathrm{Ca} = \gamma U/\mu$ is the capillary number (U being the advance velocity). It can be shown that the film is stable if the width of the layer is smaller than λ.

The case of an isolated droplet on a solid substrate is more significant for microfluidic applications, where one is typically interested in manipulating small volumes of fluid. The analysis of the drop motion is complicated by several factors compared to the continuous film. First, the freedom to change both the front and rear contact angles can act to move the drop either to the hot or to the cold side. More significantly for experiments, the quality of the surface and the wetting properties play a major role. Experiments on isolated drops require that the drop of fluid partially wets the surface, i. e. yielding a finite contact angle when placed in contact with the solid, in order to avoid the spreading of a film of liquid on the surface. However, surfaces with a finite contact angle tend to exhibit a large amount of hysteresis, which implies that the motion of the drop will be characterized by a stop-start motion unless great care is taken with the cleanliness and smoothness of the surface. Most significantly, contact angle hysteresis leads to the existence of a minimum droplet radius for motion, for a given thermocapillary stress. Above this critical value, the propagation speed increases linearly with the radius and the thermal gradient. A detailed discussion may be found in [6].

Finally, it should be noted that contact angle hysteresis may be reduced by bathing the liquid drop in another liquid. Experiments have shown that a drop of water, immersed in oil, will show a very small amount of hysteresis and may be displaced through localized laser heating [7].

T

Fluid in Suspension away from Walls

The second case is that of a drop of liquid away from any solid walls. In this case, the solid cannot be used to support the production of stresses and the presence of any thermocapillary stress produces a flow in the drop and in the surrounding fluid. This situation also produces a net force on the drop but this situation has been studied much less than that of wall contact. Homsy and his collaborators [8] have studied the migration of a long bubble in a polygonal tube under the effect of a temperature gradient. Although there is always a lubrication film which isolates the bubble from the solid walls, the fluid flow is strongly influenced by the presence of the tube, contrary to the case studied by Young et al. [4]. This allows the modelling to focus on the lubrication film between the bubble and the tube walls and the bubble velocity being computed by conservation of mass. Again, the bubble migration velocity is found to scale linearly with the imposed temperature gradient.

The modelling of an isolated drop involves the calculation of the complete flowfield around the drop in order to determine the forces acting on it. A series of recent papers by Subramanian (and collaborators) [9] have addressed the complete calculations of flow around drops in an infinite medium, taking into account the heat transport, for different ranges in the dimensionless parameters. Solutions for semi-confined geometries, such as those generally encountered in microfluidics, remain generally unavailable although recent work is heading in this direction.

Finally, it should be noted that most experiments with drops involve the presence of surfactants which serve to stabilize droplets and aid in their formation. However, surfactant dynamics and their solubility also vary with temperature. Since the effect of surfactant adsorption can be more dramatic than that of temperature, the surfactant dynamics can greatly modify the effect of temperature gradients. This is the subject of current research.

Examples of Applications

In addition to the transport of fluid, the mixing of the fluid contained inside a droplet is also a major challenge in microfluidics. The flow induced by the thermocapillary forcing has been proposed as a way to mix the contents. This was demonstrated by combining thermocapillary forcing with surface patterning in order to force a liquid layer to flow in an oblique direction with respect to the temperature gradient. The resulting motion of the liquid created recirculation zones which efficiently mix the fluid [6]. Other studies have been undertaken on an isolated drop which is pushed in a carrier fluid. Mixing is achieved in the drop if its motion leads to a breaking of the barriers to mixing, e. g. through a complex cyclical motion. Finally, merging the drops in order to produce chemical reactions by using thermocapillarity has been demonstrated. Droplets in microfluidics are difficult to merge due to the presence of a thin film which becomes harder to displace the thinner it is. This film, known as a lubrication film, prevents drops from approaching each other sufficiently to merge. However, the flow produced by thermocapillary motion has been shown to reduce this film, inducing rapid merging of the drops [10].

Definition

Thermocapillary pumping (TCP) is a pumping concept based on thermocapillary forces, where a liquid droplet moves through a microchannel or on a planar surface. A temperature gradient leads to a difference of the surface stresses across a liquid droplet and propels it into a cooler region.

Overview

According to the above definition, thermocapillary pumping concept requires an interface between dissimilar continua such as a gas/liquid interface. The molecules of a liquid attract each other due to intermolecular forces. While the molecules inside the bulk liquid experience attractive forces from all directions, the liquid molecules at the gas/liquid interface have neighboring liquid molecules only on the side facing the bulk liquid. The attractive force tends to pull the molecules at the surface into the interior. Thus, the liquid molecules at the interface will rearrange for the minimum surface energy or for the minimum number of molecules at the interface, which also means a minimum surface area. So in the three phase situation, three interfacial forces cause three-phase (solid/liquid/gas) surface tensions. The resultant force caused by these three interfacial forces will decide the final state of a liquid drop. Surface tension σ is considered as the energy required for increasing the surface area of a liquid by a unit area. Surface tension has a unit of J/m^2. Surface tension values of silicone oil in glass capillary are for instance on the order of 10^{-2} to 10^{-1} J/m^2. The surface tension of a liquid depends on the temperature. At a higher temperature, the attracting force and subsequently the surface tension decrease. For a small temperature range, we can assume a linear relation between surface tension and temperature:

$$\sigma_{lg}(T) = \sigma_{lg0} - \gamma(T - T_0) \tag{1}$$

Where σ_{lg} is the surface tension of the gas–liquid interface, γ is a constant, T is the actual temperature, and σ_{lg0} is the surface tension at the reference temperature T_0. The temperature dependency of surface tension is the fundamental concept of thermocapillary pumping.

Thermocapillary pumping offers a simple mechanism for moving drops of liquid within micro-scale channels. The advantage of TCP is its ability to locally control the movement of a single liquid drop rather than a continuous liquid stream. Furthermore, since TCP relies on simple interface heating, devices incorporating TCP can be easily constructed. These advantages make TCP a promising candidate for microfabricated chemical or biological analysis devices that require precisely defined sample volumes and that strive for a simple method for achieving system integration. The above researches have showed us the basic theoretical knowledge of TCP in different aspects which proves that the feasibility of producing TCP [1].

Basic Methodology

The actuation force for a droplet can be achieved by creating a temperature gradient along the direction of the droplet movement. The temperature difference between the two ends of the droplet can cause the different surface tensions, which will finally produce a net force to propel the liquid droplet. Volkoviski first observed that a liquid film tends to spread away from the hotter side of a substrate [2]. Hershey later observed a similar effect, where spatial variation in the film height is determined by the temperature distribution along a thin film [3]. Ludviksson and Lightfoot [4] observed the spontaneous spreading of thin, non volatile films on a vertical wettable substrate subject to a linear temperature change.

Brochard was the first to formulate a theory on the movement of a liquid droplet on a solid with a horizontal thermal gradient [5]. In his paper, reasons of the migration of the droplet under the temperature gradient were determined as the non-uniform surface tension and the different spreading coefficients S which depends on the distance x. The spreading coefficient is negative ($S < 0$) for partial wetting. The advancing velocity of the droplet is deter-

T

mined as:

$$v = C\frac{h_0}{\eta}\left[\frac{\partial}{\partial x}(\sigma_{lg}-\sigma_{sl})+\frac{\partial}{\partial x}(\sigma_{sg}-\sigma_{sl})\frac{dT}{dx} + \frac{1}{2}\frac{\partial\sigma}{\partial T}\frac{dT}{dx}\right] \quad (2)$$

Where h_0 is the thickness of the droplet at the center, σ_{lg}, σ_{sl} and σ_{sg} are the surface tension of the liquid/gas, solid/liquid and solid/gas interfaces, respectively.

Key Research Findings

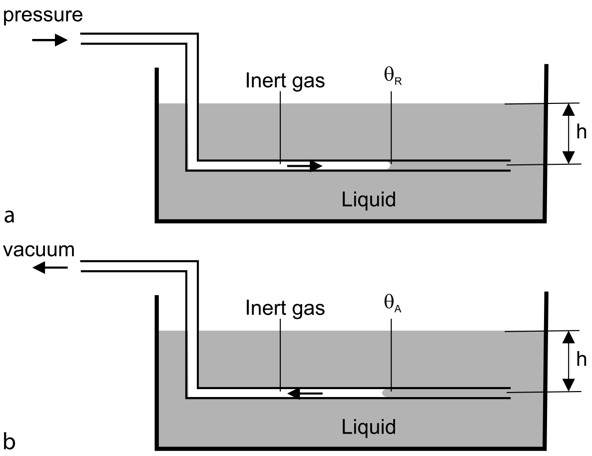
Brzoska et al. experimentally investigated displacement of liquid droplets in a temperature gradient [6]. This work focused on the different radii of the droplets. The results showed that a droplet only moves if its radius is above a critical radius R_c. The critical radius strongly depends on the contact angle hysteresis, but not on the fluid viscosity. For small liquid droplets and radii above R_c, the velocity of the droplet is proportional to the temperature gradient and inversely proportional to the viscosity η. Ford and Nadim determined the velocity and pressure fields within the droplet which is modeled as an infinitely long strip of finite width and arbitrary height profile under the uniform temperature gradient. And the boundary condition in the vicinity of contact line was highlighted [7].

Sammarco and Burns studied thermocapillary pumping of discrete droplets in micro fabricated analysis devices [8]. The major factor limits the pumping velocity is the contact angle hysteresis. Contact angle hysteresis reduces the temperature induced driving force of TCP, thereby introducing a minimum temperature difference requirement for drop movement. This minimum temperature difference is a function of the hysteresis parameter $(1 - \cos\theta_A/\cos\theta_R)$, where θ_A and θ_R are the contact angles at the advancing and the receding edges of the droplet. The greater the degree of hysteresis, the higher the minimum temperature difference needed to initiate droplet movement. When contact angle hysteresis becomes so large that the droplet may boil before moving. Surface treatment can help to reduce the contact angle hysteresis. Further, converging microchannels can offset the hysteresis and the externally applied pressure. Figure 1 shows a set up for measuring the contact angles of receding and advancing ends. Using the low-pressure air source and submerged in liquid, from the Yong–Laplace equation the contact angle can be determined as:

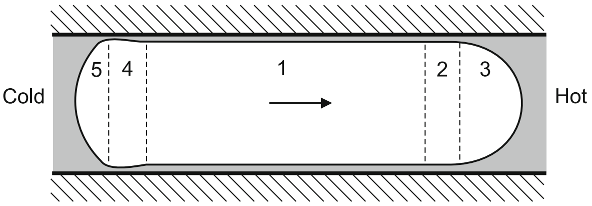
$$\theta_{A,R} = \frac{1}{\cos\left[d\,(p-\rho g h)\,d/(G\sigma)\right]} \quad (3)$$

while σ is the liquid surface tension, d is the channel diameter and G is a constant specific to channel geometry (G=4 for circular, G=2 for slit-like, and G=2(1 + height/width) for rectangular cross sections).

Besides liquid droplets, bubbles can also be pumped in microfabricated channels. Mazouchi and Homsy investigated the migration of a long bubble in a tube with a prescribed axial temperature gradient [9]. The resulting thermocapillary force moves the bubble toward the hotter region, which is opposite to the liquid droplets. The work focused on the determination the bubble velocity. A simplified model was used. The model ignores the gravity in the horizontal tube, the viscosity and the thermal conductivity of the gas. At small Reynolds numbers and capillary numbers, a theory based on the lubrication approximation and matched expansions was presented to determine the shape and speed of the bubble. The assumption of small capillary numbers and long bubbles allows the division of the domain into five regions depicted in Fig. 2. The long cylindrical region of constant film thickness is connected to two constant curvature caps through two transition regions.



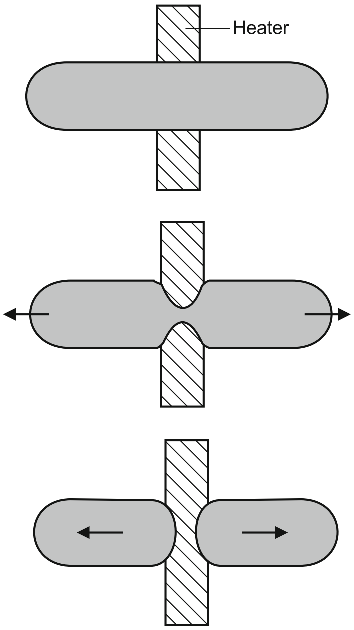
Thermocapillary Pumping, Figure 1 Experimental setup for measuring the receding (**a**) and advancing (**b**) contact angle in a microchannel



Thermocapillary Pumping, Figure 2 Section of a bubble in a horizontal tube. Five regions are shown: the constant film thickness region (1), two capillary static's regions (3, 5), and two transition regions (2, 4)

Darhuber et al. demonstrated active manipulation of nanoliter droplets on the surface of a glass or silicon substrate by combining chemical surface patterning with electronically addressable microheater arrays [10]. Hydrophilic lanes determine the possible routes for liquid migration, while the activation of a specific heater determines the trajectories. The induced temperature gradients spatially modulate the liquid surface tension by thermocapillary effect; thereby take over the control of the direction, timing, and flow rate of continuous streams or discrete drops. Temperature maps can be programmed to move, split, trap, and mix microscale volumes without mechanically moving parts. Figure 3 shows an example of droplet splitting using thermocapillary forces. The method of fluidic actuation allows direct accessibility to liquid samples for handling and diagnostic purposes and provides an attractive model for the thermocapillary pump.

Yarin et al. studied the movement of liquid droplets consisting of *n*-decane, *n*-undecane, *n*-dodecane, and *n*-hexadecane on a partially wettable cylindrical fiber [11]. When the temperature gradient was created along the fiber, the droplets began to move along the fiber toward the cold region according to the phenomenon related to the thermocapillary motion. Their theoretical results and experimental data agree reasonably well with their theories. The model of the droplet motion reveals its potential importance for a number of applications, particularly for draining filters that coalesces liquid droplets from a gas stream.



Thermocapillary Pumping, Figure 3 Splitting of a droplet using thermocapillary force. When the heater is turned on, the induced temperature gradient causes the droplet to move away from the heater. As result, the droplet is split at its center

Glockner and Naterer reported a new method of cyclic flow control with an external heat source is developed for thermocapillary pumping of a microdroplet in a closed microchannel [12]. The pumping concept involves a stationary cyclic heat source embedded within an adjoining silicon substrate. Lab on a chip based on thermocapillary pumping can be realized with this concept. The internal and external motions of micro-droplet are examined numerically using the finite-volume method and analytically using slug-flow approximation. The solution of the full Navier–Stokes and energy equations within the droplet were considered. Additionally, temperature boundary conditions for a stationary heat source are applied at the interface between the substrate and its surroundings, rather than along the microchannel wall.

Burns and Masterangelo reported microfabricated structures for integrated DNA analysis based on photolithography silicon micromachining [13]. The thermocapillary pump was able to move discrete nanoliter drops through enclosed channels using only local heating. The same actuation concept can accurately mix, measure, and divide drops by simple electronic control of the heater. In addition, they have constructed thermal-cycling chambers, gel electrophoresis channels, and radio labeled DNA detectors that are compatible with the fabrication process. Since all of the components are made by conventional photolithographic techniques, they can be integrated into a more complex system.

DeBar and Liepmann reported a silicon-based TCP with integrated microheaters [14]. The devices were operated at a variety of heater settings to evaluate their performance over a range of flow rates and pressures. A minimum energy of 140 mW was required from the central heater to generate and maintain the vapor bubble, and the flow rate increased with input energy. The efficiency of the device increased with flow rate, since the overhead to create and maintain the bubble (140 mW) dwarfs the energy expended to generate the temperature gradient (15 – 50 mW). The devices generated a maximum pressure head of 44 Pa, and a maximum flow rate of 9.3 nL/s.

Future Directions for Research

Despites its simplicity in implementation, thermocapillary pumping was not fully exploited in microfluidics research community. Thermocapillary may have a big impact in droplet-based digital microfluidics. Besides droplet transport, thermocapillary force can be used for other droplet manipulation functions such as splitting, merging and dis-

pensing. More research results in this direction can be expected in the near future.

Thermocouples

Definition

A thermocouple is a measuring device consisting of two different metals or semiconductors, commonly performed as wires, which are connected in one point. Because of the Seebeck-effect an electrical voltage can be measured between the two metals as long as the junction and the free ends of the wires have different temperature levels. The voltage is almost linear with the temperature difference and lies for metals in the range of some micro-volts per Kelvin.

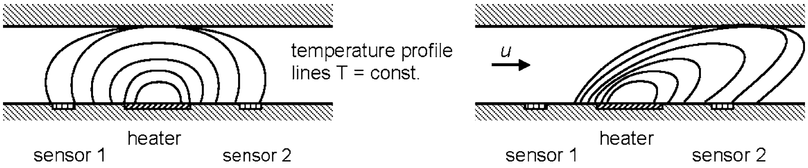
Thermoelectric flow sensors indirectly measure the velocity of gases and liquids close to the wall and the volume flow rate in a microchannel. Electrical heating, thermoelectric temperature sensing, appropriate calibration, and



Thermoelectric Flow Sensors, Figure 1 Setup of a thermoelectric flow sensor in a channel consisting of a heater and two temperature sensors upstream and downstream of the heater, method A; *left*: conductive heat transfer with symmetric temperature profile; *right*: convective heat transfer with higher temperature at sensor 2

sensor control are essential for fast, reliable and sensitive measurement.

Overview

Flow measurement using thermoelectric devices and sensors implies the use of heat transfer and temperature measurements in microchannels to determine the near-wall velocity. With appropriate calibration procedures, the mean flow velocity or mass flow rate can be determined by measurements of the local wall temperature. Thermoelectric temperature probes and sensors, also known as thermocouples, rely on the Seebeck effect, where a temperature difference between two metal contacts induces a voltage drop which can be measured. An electrical resistance heater introduces a heat flux into the fluid flow. The temperature is measured either directly at the heater, in its vicinity, or at the wall downstream of the heater. Often, the upstream mean temperature of the fluid flow is also measured to provide a comparison. Thermoelectric flow rate measurement is one of commonest, and for laminar flow one of the most accurate, reliable, and cost-effective measuring techniques.

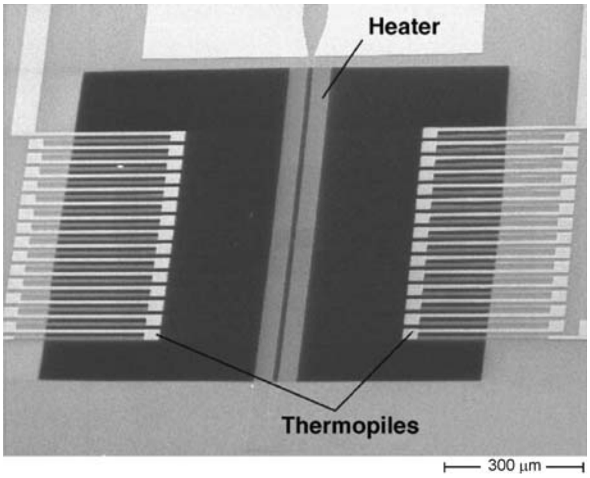
Basic Methodology

The flow sensor consists mainly of the heating element and temperature sensors, which measure the temperature of the heater or of the fluid before and after the heater. The streaming fluid is mainly heated by resistance heaters. The temperature can be measured either by electrical resistance sensors or by thermocouples. This essay concentrates on the latter method for thermoelectric flow sensors.

Thermoelectric temperature measurement has been established for more than a century, and the sensing devices, including thermocouples, have been miniaturized from the start. Van Herwaarden and Sarro [1] presented thermoelectric flow sensors, which were then adopted in the textbook by Middelhoek and Audet [2]. The basic measuring principle was not changed but was modified and improved by the choice of different materials, geometry, and device design. The basic sensor setup can be classified into two different techniques or methods. In method A, heating of the fluid imposes a temperature profile in the channel or near-wall flow (see Fig. 1), which is measured at certain positions by thermocouples. In method B, fluid flow cools the heater, the temperature or electrical power of which is measured (see Fig. 2). Besides the integral heater temperature, the local temperatures of a heated area can be measured, which allows a direction-sensitive velocimetry (see Fig. 3).

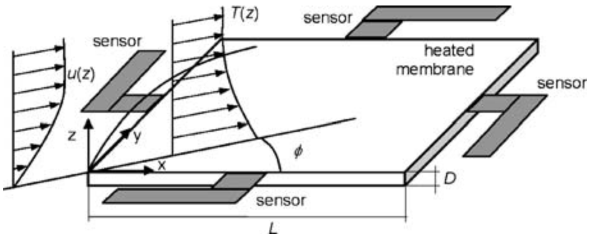
In method A, the temperature downstream of the heater is taken to determine the mean flow velocity in the vicinity of the heater. The general setup is shown in Fig. 1. The geometric setup of the heater and sensors determines the measurement of the fluid flow.

The temperature profile in the microchannel without fluid flow is nearly symmetric, and both sensors are detecting a similar temperature. The fluid flow shifts the temperature profile downwards, and the sensor located downstream measures a higher temperature; the sensor located upstream measures the temperature of the incoming fluid. The temperature distribution has been simulated by Ashauer et al. [3].



Thermoelectric Flow Sensors, Figure 2 Thermoelectric flow sensor consisting of an electrical heater on a thin membrane with parallel meandering thermoelectric sensors, two thermopiles with 15 thermoelements [4]

T



Thermoelectric Flow Sensors, Figure 3 Two-axis flow measurement from convective cooling of the sensor device with connected temperature sensors and direct heating of the membrane, acc. van Oudheusden [7]

The geometric setup of a fabricated device in thin film technology (see Fig. 2) is an example of method B. The heating structure with the adjacent meandering thermopiles to measure the temperature is located on a thin membrane to reduce the heat losses to the wall material. The thermocouples are arranged in a pile (series switching) to increase the sensitivity of the sensor used to measure the temperature difference between the heater and the substrate. A good example of the microstructure device has been given by Buchner et al. [4] (see Fig. 2).
A different scheme with a periodic heater/sensor setup was proposed by Al khalfioui et al. [5] with a more detailed flow measurement. This system is more complex and the effort required to measure the physical domain is correspondingly greater.
Measurement of the flow by a heated membrane with connected thermocouples has been proposed by van Oudheusden [6, 7]. The schematic setup is shown in Fig. 3. Comparing the four measured temperatures allows not only measuring the flow near the wall, but can also determine the angle of attack of the main direction of flow. More details of the analysis have been given by van Oudheusden [7]. The sensor contacts also serve as mechanical hinges and guarantee a good thermal insulation for the heated membrane.
For commercial flow sensors, the in-line setup according to method A with one heater and two sensors, one upstream and one downstream, is the most important and has been commercially realized by sensor suppliers.

Key Research Findings

General Setup

The geometric setup has been explained in the section on basic methodology. The general requirements of the signal processing are now described. The domain of the mechanical signal to be measured is determined by the flow and the velocity profile near the wall and the heating/sensing device. The flow-induced heat transfer (convection) and the parallel heat conduction in the sensor wall/substrate interface determine the measured temperature. Comparison of two or more temperatures indicates the flow and can be transferred into a flow rate, thus giving the complete flow situation. The temperature is measured as a voltage between the hot and cold ends of the thermocouple [6]. With this setup, three complex domains are combined: fluid flow, heat transfer, and thermoelectric energy and signal conversion.
In the following, we will start with the fluid flow and convective heat transfer, followed by the temperature measurement and will then characterize the entire device.

Heat Transfer and Fluid Flow

The electrical power dissipated in the heater spreads into the flowing fluid and the wall or substrate supporting the heater and sensors. In a steady-state situation, the energy balance of the heater/sensor expresses the correlation between the electrical heating power P and the heat dissipated into the substrate Q_S and into the fluid Q_f

$$P = Q_\mathrm{S} + Q_\mathrm{f} = G_\mathrm{S}\,(T_\mathrm{H} - T_\mathrm{S}) + G_\mathrm{f}\,(T_\mathrm{H} - T_\mathrm{f}) \qquad (1)$$

where T_H, T_S, and T_f are the temperature of the heater, the substrate, and the bulk fluid, respectively. The coefficients G_S and G_f indicate the thermal conductivity of the substrate and the convection by the flowing fluid, respectively. Due to the small temperature differences, radiation heat transfer can be neglected in most cases. The flow measurement relies on the variance of G_f with the flow and is measured, for example, by the temperature difference induced by a given electrical power.
As already mentioned, the flow rate can be determined by measuring the temperature of either the heater (method B) or the fluid downstream of the heater (method A). In both cases, the temperature of the fluid upstream of the heater must be known or must be set to the ambient temperature. First, we focus on measuring the fluid temperature downstream of the heater according to method A.
The wall heat transfer from the heater determines the energy used for heating the fluid and increasing its temperature. The location of the temperature sensor influences the measurement and should not be too far downstream from the heater. If the inflowing fluid has the same temperature as the sensor substrate, T_S, and the sensors measure the mean temperature of the fluid, the energy dissipation into the fluid is determined by

$$Q_\mathrm{f} = \dot{m}\,c_\mathrm{p}\,(T_\mathrm{S} - T_\mathrm{f}) \qquad (2)$$

where the mass flow rate $\dot{m} = \rho_\mathrm{f} A_\mathrm{C}\, u$ and c_p is the heat capacity of the fluid. The density of the fluid ρ_f and the

channel cross-section A_C should be known in order to obtain the correct sensing. The mean flow velocity u is determined with the heater power and the measured temperature difference

$$P = Q_S + \rho_f c_p A_C \,(T_S - T_f)\; u \tag{3}$$

where the heat dissipation into the substrate Q_S has to be estimated. The measurement of the fluid temperature downstream is not very accurate, so the fabricated sensor always has to be calibrated.

Convective cooling of an electrical heater and measuring its temperature according to method B avoids some sources of error, like measuring the heated fluid temperature or the unknown amount of heat dissipated into the substrate. For this reason, many sensors are located on a thin membrane or are fabricated on polymers or on other thermal insulations. This minimizes the parasitic heat loss and increases the sensor's accuracy. The convective heat transfer into the fluid Q_f is determined by the heat transfer coefficient α_W at the wall and by the temperature difference.

$$\frac{Q_f}{A_H} = q_f = \alpha_W \,(T_H - T_f) \tag{4}$$

The cooling heat transfer of the electrical heater can be treated like cooling a plate on one side in surface flow. Here, the influence of the surrounding channel walls is neglected for simplicity. With the help of the boundary layer theory, the wall heat transfer is described by the dimensionless heat transfer coefficient, the local Nusselt number Nu [7]

$$\mathrm{Nu} = \frac{\alpha\, x}{\lambda_f} = 0.332\, \mathrm{Pr}^{\frac{1}{3}} \mathrm{Re}^{\frac{1}{2}} \tag{5}$$

which has the dimensionless fluid properties (Prandtl number) $\mathrm{Pr} = \lambda_f / \rho_f\, c_{p,f}$ and dimensionless flow conditions (local Reynolds number) $\mathrm{Re} = u\,x/\nu$. For the entire length of the heater, l_H, the overall $\mathrm{Nu_L}$ number has been given by Welty et al. [8].

$$\mathrm{Nu_L} = \frac{\alpha\, l_H}{\lambda_f} = 0.664\, \mathrm{Pr}^{\frac{1}{3}} \mathrm{Re}^{\frac{1}{2}} \tag{6}$$

Both equations are valid for laminar flow with $\mathrm{Re} = u\,x/\nu < 2 \times 10^5$. The correlation between the flow velocity and the dissipation power and measured temperature difference is given by

$$\begin{aligned}\frac{Q_f}{A_H} &= \frac{\mathrm{Nu}\,\lambda_f}{l_H}\,(T_H - T_f)\\ &= 0.664\,\lambda_f\,\mathrm{Pr}^{\frac{1}{3}} \left(\frac{u}{l_H\,\nu}\right)^{\frac{1}{2}} (T_H - T_f)\end{aligned} \tag{7}$$

where the length coordinate x replaces the heater length, l_H. Arranging the above equations the correlation of the electrical heating power with the flow velocity gives the following equation:

$$\begin{aligned}P &= G_S\,(T_H - T_S)\\ &\quad + 0.664\,\lambda_f\,A_H\,\mathrm{Pr}^{\frac{1}{3}} \left(\frac{u}{l_H\,\nu}\right)^{\frac{1}{2}} \cdot (T_H - T_f)\end{aligned} \tag{8}$$

The detailed analysis of the correlation needs many parameters such as: the heat conductivity of the substrate, the correct fluid properties, and the correct geometry of the sensor. For practical applications, the correlation between the electrical power, the measured temperature difference, and the flow velocity can be reduced to

$$P = \left(c_1 + c_2\sqrt{u}\right)\,\Delta T \tag{9}$$

for laminar flow with $\Delta T = T_H - T_f$ [9]. Both coefficients can be determined by calibration measurements and should not vary with time or flow velocity. However, the fluid properties have to be calibrated to obtain the correct measurements. The operation of the device with different measuring modes is described in the section about the design, fabrication, and operation of the devices.

Temperature Measurement by Thermoelectric Effect

Due to their compactness and standard fabrication technology, the temperature in thermal flow sensors is often measured by thermocouples, which rely on the thermoelectric effect. The thermoelectric effect describes the coupling between the electrical and thermal currents, especially the occurrence of an electrical voltage due to a temperature difference between two material contacts, known as the Seebeck effect. In reverse, an electrical current can produce a heat flux or a cooling of a material contact, known as the Peltier effect. A third effect, the Thomson effect, is also connected with thermoelectricity where an electric current flowing in a temperature gradient can absorb or release heat from or to the ambient [10, 11]. The relation between the first two effects can be described by methods of irreversible thermodynamics and the linear transport theory of Onsager in vector form.

$$\begin{bmatrix} q_{el} \\ q_{th/T} \end{bmatrix} = \begin{bmatrix} \sigma_{el} & L_S \\ L_P & L_q \end{bmatrix} \begin{bmatrix} \Delta U \\ \Delta T \end{bmatrix} \tag{10}$$

The electrical current density q_{el} and the thermal entropy flux q_{th}/T are linked to the driving forces, the temperature gradient ΔT and the potential gradient ΔU with linear coefficients: σ_{el} as the electrical conductivity, L_q for

T

the heat transfer, L_S for the Seebeck effect, and L_P for the Peltier effect.

Solving the first equation for ΔU and substituting the result into the second equation yields

$$-\Delta U = \frac{q_{el}}{\sigma_{el}} + \frac{L_S}{\sigma_{el}} \Delta T \tag{11}$$

$$q_{th} = T \frac{L_P}{\sigma_{el}} q_{el} + T \left(\frac{L_S L_P}{\sigma_{el}} - L_q \right) \Delta T \tag{12}$$

The matrix in Eq. (10) is symmetrical according to the Onsager reciprocity law [11], which means $L_S = L_P$. The linear coefficients can be identified with known material properties

$$\rho_{el} = \frac{1}{\sigma_{el}} \tag{13}$$

$$\lambda_{th} = -T \left(\frac{L_S L_P}{\sigma_{el}} - L_q \right) = -T \left(\frac{2 L_S}{\sigma_{el}} - L_q \right) \tag{14}$$

$$\alpha_{ab} = \frac{L_S}{\sigma_{el}} \tag{15}$$

$$\pi_{ab} = T \frac{L_P}{\sigma_{el}} \tag{16}$$

The thermoelectric temperature measurement employs the Seebeck effect, the voltage between two material pair contacts on a different temperature level without the flow of electrical current ($Q_{el} = 0$). The Seebeck effect can also be described by the correlation

$$\Delta U = (\alpha_a - \alpha_b)\ \Delta T = \alpha_{ab}\ \Delta T \tag{17}$$

where α_{ab} is the Seebeck coefficient for the material pair a – b. The Seebeck coefficient depends on the pair of materials. Certain applications, like sensing or energy conversion, demand certain parameter combinations like heat or electrical conductivity or temperature linearity. For temperature measurement, standardized elements and pairs of materials are used which have good linearity of the material properties, reproducibility, and long-term stability.

A summary of the common standardized thermocouples is given in Table 1. Besides the thermoelectric properties of the Seebeck coefficient, the thermal and electrical conductivities are important for the sensitivity and time response of the thermoelectric flow sensor.

The materials of standardized thermocouples are rarely used in microfabrication, which relies to a large part on CMOS technology. Table 2 lists the metals commonly used in microfabrication. Van Herwaarden [1] and Rowe [11] have also given a summary of microthermocouple materials. Often, the thermoelectric pairs of materials are used for energy conversion from heat to electricity with the help of thermoelectric generators. Here, the so-called figure-of-merit, Z, gives an indication of a good energy conversion and is given by

$$Z = \frac{\alpha_{ab}^2}{\left(\sqrt{\lambda_a \rho_a} + \sqrt{\lambda_b \rho_b}\right)^2} = \frac{\alpha_{ab}^2 \sigma_a}{\lambda_a} \tag{18}$$

The second part of Eq. (18) is often used to characterize the thermoelectric activity of a single material α. This parameter may help to identify sensitive pairs of materials for thermoelectric temperature measurement.

Due to its use in microelectronics, silicon is by far the most common and best understood semiconductor material. It is cheap and a large variety of fabrication processes are available. Consequently, silicon has become a common material for thermoelectric sensors. The material properties of silicon depend heavily on the doping concentration and type as well as on the fabrication process [9].

A comparison of the values in Tables 3 and 4 gives remarkable differences between the bulk material and the deposited film material. Baltes et al. [9] have given the properties of n- and p-doped silicon together with the fabrication process, which also differs over a wide range. The doping concentration determines the thermoelectric properties of silicon over a wide range [12, 13]. For practical

applications it is very important to characterize the fabrication process and the relevant outcome and to ensure the reproducibility of the properties of the material.

Design, Fabrication, and Operation of Devices

Not only the single sensor components like heater or sensor, but also the interplay of the parts, their integration and the entire device are important for the performance of the sensor. Table 5 gives the general relationship between the film and bulk properties of the sensor and the sensing characteristics.

The more generalized parameters of the thermal conductance, G, and the temperature conductivity, C, are a function of the sensor geometry and the heat and temperature diffusivity. The device parameters and characteristics are determined by the properties such as the thermal conductivity or the Seebeck coefficient of the thermoelectric materials as well as the geometric setup and fabrication method. The main sensor signal output is determined by the number of thermocouples n, the Seebeck coefficient, and the measured or applied temperature differences. With a higher temperature difference, the signal increases with the heat loss. Hence, the sensitivity of the sensor depends mainly on the properties of the thermocouple, and the thermal conductance of the fluid and the substrate. For gas flow measurement and high temperature differences, the emissivities of the heater, thermocouple, and substrate have to be considered.

The necessary power for a clear and noise-free signal can be determined from the noise of the electrical conductivities and the sensitivity of the sensor. The inverse ratio gives the detectivity of the sensor. The time constant of the sensor, which determines the response time to flow changes or the start-up time of the sensor, is a function of the thermal diffusivity of the heater, thermocouple(s), and the substrate, as well as the thermal conductance of the entire device.

In summary, a high Seebeck coefficient and high electric conductivity of the sensor as well as low thermal conductance of the sensor and the substrate provide a sensitive, low energy-consuming sensor with a fast response time. Hence, the figure-of-merit (Eq. (18)) of a thermoelectric flow sensor is a good indicator of quality. However, the heater and sensor are often fabricated in thin-film technology on membranes, glass, or polymer substrates. The material combinations of the devices must also guarantee low thermal stress due to the expansion of heating and

cooling. Table 6 gives the thermal and electrical properties of some sensor materials.

Besides the properties and the geometrical setup, the operating mode of the sensor device is important for the application and sensitivity. The heater can be operated in two modes [16]: with constant electrical power or at a constant controlled temperature. With constant electrical heating power, the measurement of the temperature difference ΔT is appropriate for low liquid flow rates or gas flow. No temperature control is necessary for the heater. The heater cannot be overheated when an error occurs. Measuring the heater temperature T_{H} is suitable for liquid flow rates, but the fluid temperature has to be known. With a constant heater temperature, the measurement of the temperature difference ΔT can detect very low liquid flow rates and gas flow. Measuring the heating power is applicable for medium liquid flow rates. Due to the fast signal response, this mode can also be used to investigate the flow behavior. During to the longer operating time, thermal drift of the sensor or time drift of the thermocouple may occur and should be controlled by the routine calibration procedures.

The electrical insulation of the heater and the sensors is not critical when designing gas flow sensors, but has to be considered for liquid flows. In many cases, insulating layers, like metals oxide or polymer films, are deposited on the surface of the electrical conducting layers. Many thermoelectric flow sensor devices have been designed and fabricated for investigation and research purposes, but some are already commercially available. An overview of the existing devices has been given by Dittmann [15], but does not claim to be complete (see Table 7).

Dittmann's [15] estimation of the costs may serve as a reference point. In the fast developing area of sensor technology, costs can change rapidly. Future improvements in fabrication technology and new emerging markets may change the price level of existing sensors or produce new types of thermoelectric flow sensors.

Future Directions for Research

The most important requirements for successful sensors are accuracy, good reliability, and long-term operability at an acceptable price. Many applications may require standard sensors, but tailor-made solutions and integrated devices in Lab-on-a-Chip or microprocess technology application are also urgently needed. A standardization

of sensing elements and entire devices will help developers and users in many areas. Besides the typical materials, which might already be standardized, like thermocouples or heater materials, the standardization of typical geometries of the heater/sensors and the sensor setup would be very helpful for future developments and applications. The integration of sensing elements into various materials like metals, polymers, glass, or ceramics is very important for the wide application of the flow sensors in chemical or thermally challenging environments. An intelligent three-dimensional setup of the heater and the sensors elements may help to achieve more accurate measurements. For long-term application, an automated calibration procedure is desirable and will give a user-friendly sensor.

Thermal mechanical valves; Thermally actuated mechanical valves; Thermally driven mechanical valves

Definition

A thermomechanical valve is a device that regulates fluid flow (either gas flow, liquid flow or slurry flow) by using an actuator which deforms under different temperatures to open, close, or partially obstruct various channels.

Overview

Since Kilby, the 2000 Nobel Prize winner, proposed the first integrated circuit in 1958, microfabrication has been a very attractive topic in a wide range of research fields. In the late 1970s, influenced by the development of microfabrication technology, microelectromechanical

systems (MEMS) began to flourish in every mechanical field and about 10 years later largely drove the development of microfluidic chips. A typical microfluidic chip is a piece of glass or plastic plate with a network of microchannels, electrodes, and electrical circuits integrated onto it to perform a series of chemical or biomedical diagnoses and analyzes such as: DNA separation, enzymatic analysis, bacterial diagnosis etc. Normally, the volume of liquid that a microfluidic chip deals with is in the range of a nanoliter to a picoliter. The small volume requirement together with other advantages benefiting from miniaturization, such as short analysis time, high throughput, and minimized Joule heating, make such small-scale devices more competitive than their traditional counterparts. There are several commonly used methods to manipulate the liquid in a microfluidic chip including both mechanical and nonmechanical approaches, such as electrokinetic, magnetic, and electrochemical methods. Different approaches will lead to the development of different microvalves, which can be categorized as active or passive valves. Under each of the above category, microvalves can be further classified into mechanical or nonmechanical valves. Typical examples of active mechanical microvalves include, but not limited to, magnetic valves, electric valves, thermal valves, and piezoelectric valves. Active nonmechanical microvalves include phase change valves, bistable valves, and electrochemical valves, etc. Here we will focus on the introduction to thermomechanical microvalves including both active and passive valves, which use heat to conduct mechanical actions.

Generally, the chemical and physical properties of most engineering materials vary with temperature. The only difference lies in the degree to which the property changes with temperature. Among all the properties, the material shape change with temperature has mostly been used for the development of thermomechanical microvalves. The detailed mechanisms of thermomechanical microvalves will be discussed below. Briefly, the deformation of the material shape causes an actuation force, which can be used to induce mechanical actions through actuators. The thermomechanical microactuator is the major component of a thermomechanical microvalve through which thermal energy is converted into mechanical stress. The induced mechanical stress causes the deformation of the material shape of the actuator to close or open a channel. There are two main mechanisms for a thermomechanical actuator to convert thermal energy into mechanical stress: thermal expansion and the shape memory effect. Thermal expansion means that the size of a piece of material expands when its temperature increases and the shape memory effect describes a phenomenon that a piece of material memorizes its original shape and tends to return to it when heated. To control the switch between open and closed, a heater or a cooler is usually also involved in a thermomechanical microvalve. According to the way that the thermal control affects the shape of the microactuator, thermomechanical microvalves can be roughly divided into three categories: thermal expansion microvalves, bimetallic microvalves, and shape memory alloy (SMA) microvalves.

Basic Methodology

Different thermomechanical microvalves use different mechanisms to control the valve although all of them are based on the deformation of the material due to thermal expansion. For example, a thermal expansion microvalve utilizes the thermal expansion of a single material to open or close the flow, a bimetallic microvalve utilizes the thermal expansion difference between two materials which are bond together to open or close the flow, and a thermally driven SMA microvalve utilizes the shape memory effect (a sample of SMA has the capability to regain its original geometry by itself during heating (one-way effect)) to open or close the flow. The detailed methodologies for each category are summarized below.

Thermal Expansion Microvalves

Thermal Expansion

For most materials, when heated, the average amplitude of the atom's vibration within it increases, which increases the distance between the atoms thus causing the material to expand. Early developed thermomechanical microvalves, including bimetallic microvalves, were primarily based on

this principle. In contrast to bimetallic microvalves, only one single-layered beam or membrane is usually involved in a thermal expansion microvalve. Generally, two coefficients are used to depict the thermal expansion in a piece of material: the linear thermal expansion coefficient, α, and the volumetric thermal expansion coefficient, β. These two coefficients relate the change in temperature to the change in the linear and volumetric dimensions of the material, respectively, and are defined as

$$\alpha = \frac{1}{L}\frac{\partial L}{\partial T}\,, \tag{1}$$

$$\beta = \frac{1}{V}\frac{\partial V}{\partial T}\,, \tag{2}$$

where L and V are the length and the volume of the material, respectively, and T is the absolute temperature. For ideal isotropic materials, the linear thermal expansion coefficient is one-third of the volumetric thermal expansion coefficient, i.e., $\alpha = (\beta/3)\,\beta$. For most materials, both coefficients are positive, for example, they expand when heated. Assuming that the linear thermal expansion coefficient is independent of the temperature, the length of the material under zero compressive stress can be simply given as

$$L = L_0\left[1 + \alpha\,(T - T_0)\right]\,, \tag{3}$$

where L_0 is the length of the material at a temperature, T_0.

Beam Buckling

If fixed at its two ends, a straight beam will bend when heated due to thermal expansion. This inflection is usually utilized to design a thermal expansion microvalve actuator and the degree to which the material inflects when heated is key to the valve design. Lin et al. [1] have developed a theoretical model to investigate the buckling under electrothermal buckling conditions. Figure 1a shows a schematic diagram of such a microbeam. The deflection at the center of the beam can be given as

$$h_{\max} = 4\zeta\sqrt{\frac{I}{(\alpha\Delta T - \varepsilon)\,A_c}}\,, \tag{4}$$

where A_c represents the cross-sectional area, I is the inertia moment of the beam, T is the average temperature, ε is the strain of the beam, and ζ is a function of the maximum deflection angle, $\theta_{\max}$, which occurs at one-fourth of the total length, given by

$$\zeta = \sin\frac{\theta_{\max}}{2}\,. \tag{5}$$

There are two important parameters involved in the evaluation of the beam buckling, which are the critical load, P_{cr}, and the critical temperature, T_{cr}. The critical load is the force at which the beam will buckle, given by

$$P_{cr} = \frac{4\pi^2 EI}{L^2}\,, \tag{6}$$

where E is the Young's modulus. If no stress and external pressure differences are loaded on the beam at the temperature, T_0, considering a constant linear thermal expansion coefficient, the theoretical critical temperature for the beam to buckle can be given as

$$T_{cr} = \frac{4\pi^2 I}{\Delta\alpha A_c L^2} + T_0\,, \tag{7}$$

where $\Delta\alpha$ is the difference in the thermal expansion coefficient between the beam and the substrate. Investigations on thermal buckling of eccentric clamped–clamped beams can be found elsewhere [2].

Membrane Buckling

Similar to beam buckling, membrane buckling is another important mechanism for thermal expansion microvalves. To investigate the bending of a membrane when heat is added to it, Fig. 1b illustrates the principle of the thermal buckling of a square membrane. Considering a uniform compression condition cross the membrane (i. e., the compressive stress is constant, $S_x = S_y = S$), the membrane buckles transversally without any additional external load when the compressive stress gradually increases with temperature and exceeds the critical stress, S_{cr}. The critical stress is defined as

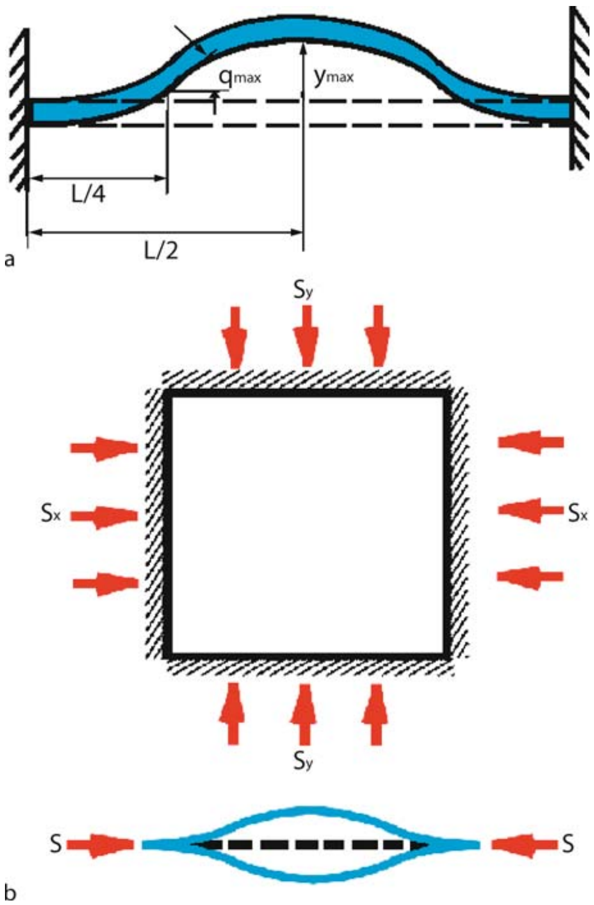
$$S_{cr} = 4.38\frac{\delta^2}{l^2}\frac{E}{1-\nu^2}\,, \tag{8}$$

where l and δ are the length (or the width for a square membrane) and the thickness of the membrane, respectively, and ν is Poisson's ratio. After that, a higher temperature will give rise to a larger buckling amplitude. The following equation shows the transversal displacement of the buckled membrane:

$$h(x,y) = \frac{h_{\max}}{4}\left(1+\cos\frac{2\pi}{l}x\right)\left(1+\cos\frac{2\pi}{l}y\right)\,, \tag{9}$$

where $h_{\max} = h\,(0,0)$, is the deflection at the center of the membrane. If no initial deflection is loaded and only the

T



Thermomechanical Valves, Figure 1 (**a**) Schematic diagram of a straight, clamped–clamped beam after buckling; (**b**) illustration of the thermal buckling of a square membrane

first-order buckling of the membrane is considered, $h_{\max}$ can be obtained as

$$h_{\max} = \begin{cases} 0\,, & S \le S_{cr} \\ \pm 2.298\delta\sqrt{\dfrac{S}{S_{cr}} - 1}\,, & S \ge S_{cr}\,. \end{cases} \tag{10}$$

If no stress and external pressure are loaded on the membrane at the temperature, T_0, considering a constant linear thermal expansion coefficient, the theoretical critical temperature for the membrane to buckle can be given as

$$T_{cr} = 4.38 \frac{\delta^2}{l^2\left(1 - \nu^2\right)\Delta\alpha} + T_0\,, \tag{11}$$

where $\Delta\alpha$ is the difference in the thermal expansion coefficient between the membrane and the substrate.

Sealed Capsule Expansion Microvalves

In 1987, Zdeblick and Angell [3] first proposed the concept of the sealed capsule expansion (SCE) valve, which utilized the thermal expansion of a trapped liquid to actuate the valve, instead of the buckling of a beam or membrane. Later, a family of sealed capsule expansion valves trademarked as the *FluistorTM* was developed by Redwood Microsystems. Generally, in a SCE microvalve, there is a small cavity with trapped liquid which has a low boiling point and/or a high expansion coefficient. When the liquid is heated, it expands and closes the valve. When it is cooled, it shrinks and opens the valve.

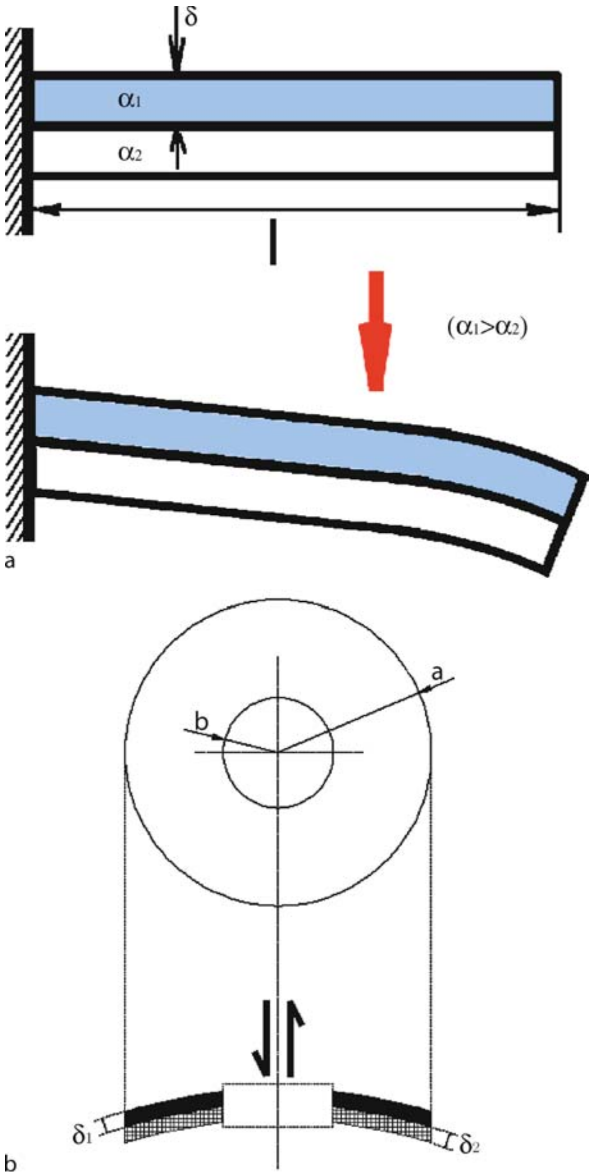
The cavity can be made of silicon, quartz, or glass substrates or any other appropriate materials. Because of the convenience of silicon micromachining techniques, silicon is commonly used to fabricate the cavity and flexible membrane. Normally a thin-film heating resistor is integrated onto one inner side of the cavity, with a flexible diaphragm wall sealing the opposite inner side of the small cavity. When an electrical current is passed through the resistor, the trapped fluid is heated to evaporate and expand. The expansion causes the flexible wall to flex outward. This outward flex movement is then used to close or open the flow. A SCE microactuator can function as a normally opened microvalve, which opens the channel in its normal de-energized state. At a normal temperature, the flexible wall is in its shrinking stage, which gives a gap between the valve seat and the flexible wall. The valve is in its open stage with the fluid moving through the gap. When the trapped liquid is heated, due to its thermal expansion, the outward-flexing wall comes into contact with the nearby valve seat. Thus the fluid flow is cut off between the input channel and the output channel through the port. A high power can be applied to speed up the closure. Because the cooling is slower than the heating for most thermally driven valves, the following opening is much slower and depends on the thermal conduction and convection in the valves.

Bimetallic Microvalves

Bimetallic Strip

A bimetallic strip was the earliest bimetallic valve structure and was invented by the eighteenth century British clockmaker John Harrison for his third marine timekeeper (H3) to compensate for the error caused by temperature. A bimetallic strip consists of two strips of different metals which have different thermal expansion coefficients. As shown in Fig. 2a, if two strips are bonded together

throughout their length, due to the different degrees of thermal expansion between the two metals, the bimetallic strip will bend to the side with a lower thermal expansion coefficient when heated and to the other side when cooled down. The sideways displacement of the bimetallic strip is much larger than the lengthways change in either of the two metal strips. Thus, a temperature change is converted into a sideways mechanical displacement, which can be used to regulate the flow. For two layers of different thickness, as shown in Fig. 2a, the sideways displacement can



Thermomechanical Valves, Figure 2 (**a**) Cross-section of a bimetallic strip; (**b**) schematic of a circular annular bimetallic membrane

be given as

$$h = \frac{3L^2(\alpha_2 - \alpha_1)\,\Delta T\,(\delta_1 + \delta_2)}{\delta_2^2 K_1}\,, \tag{12}$$

where

$$K_1 = 4 + 6\frac{\delta_1}{\delta_2} + 4\left(\frac{\delta_1}{\delta_2}\right)^2 + \frac{E_1}{E_2}\left(\frac{\delta_1}{\delta_2}\right)^3 + \frac{E_2}{E_1}\frac{\delta_2}{\delta_1}$$

and the subscript, i, represents the ith strip. If the thicknesses of the two layers are equal, i. e., $\delta = \delta_1 = \delta_2$, the sideways displacement can be simplified as

$$h \approx \frac{6L^2(\alpha_2 - \alpha_1)\,\Delta T E_1 E_2}{\delta\left(E_1^2 + E_2^2 + 14E_1E_2\right)}\,. \tag{13}$$

Neglecting the difference between E_1 and E_2, the displacement can be further simplified as

$$h \approx \frac{3}{8\delta}(\alpha_2 - \alpha_1)\,\Delta T L^2\,. \tag{14}$$

Bimetallic Membrane

In addition to bimetallic strips, bimetallic membranes are also commonly used in a microvalve actuator. Figure 2b shows the schematic of a circular annular bimetallic membrane. Similar to a bimetallic strip, a bimetallic membrane consists of two layers of different metal materials which have different thermal expansion coefficients. When heated, due to their different thermal expansions, the center of the membrane bulges vertically to the side with a higher thermal expansion coefficient. As shown in Fig. 2b, for a circular annular bimetallic membrane, if the outer edge is fixed by a wall and the inner edge is guided in the vertical direction by a boss, the displacement at the inner edge can be given as

$$h \approx \frac{3(\alpha_2 - \alpha_1)\,\Delta T\,(\delta_1 + \delta_2)\,(1 + \nu_a K_3/K_2)\,a^2 b^2 \ln\frac{a}{b}}{\delta_2^2 K_4\left(a^2 - b^2\right)}\,, \tag{15}$$

where

$$K_2 = 1 + \frac{E_2\delta_2^3\left(1-\nu_1^2\right)}{E_1\delta_1^3\left(1-\nu_2^2\right)} + \frac{3\left(1-\nu_1^2\right)(1+\delta_2/\delta_1)^2(1+E_1\delta_1/E_2\delta_2)}{(1+E_1\delta_1/E_2\delta_2)^2-(\nu_1+\nu_2E_1\delta_1/E_2\delta_2)^2}, \quad (16)$$

$$K_3 = 1 + \frac{\nu_2E_2\delta_2^3\left(1-\nu_1^2\right)}{\nu_1E_1\delta_1^3\left(1-\nu_2^2\right)} + \frac{3\left(1-\nu_1^2\right)(1+\delta_2/\delta_1)^2(1+\nu_2E_1\delta_1/\nu_1E_2\delta_2)}{(1+E_1\delta_1/E_2\delta_2)^2-(\nu_1+\nu_2E_1\delta_1/E_2\delta_2)^2}, \quad (17)$$

$$K_4 = 4 + 6\frac{\delta_1}{\delta_2} + 4\left(\frac{\delta_1}{\delta_2}\right)^2 + \frac{E_1\delta_1^3(1-\nu_2)}{E_2\delta_2^3(1-\nu_1)} + \frac{E_2\delta_2(1-\nu_1)}{E_1\delta_1(1-\nu_2)}, \quad (18)$$

where a and b are the outer and inner radius of the membrane, respectively. Considering $\delta = \delta_1 = \delta_2$, $E_1 = E_2$, and $\nu = \nu_1 = \nu_2$, the displacement can be simplified as follows:

$$h = \frac{3}{8\delta}(\alpha_2 - \alpha_1)\Delta T(1+\nu)\frac{a^2b^2}{a^2-b^2}\ln\frac{a}{b}. \quad (19)$$

Further numerical and experimental studies on the thermal behavior of other more complex bimetallic membranes can be found elsewhere [4].

Thermally Driven SMA Microvalves

The SMA, known as the memory metal or smart wire, was first discovered in an Ag – Cd alloy in 1932. Due to a crystalline transformation between a high temperature austenite phase and a low temperature martensite phase, when materials with this shape memory property are subject to deformation, they are able to return to their *memorized* original shape after being heated to a temperature above their transformation temperatures. It was not until the early 1960s that SMAs showed their real importance when the Ni – Ti SMA was discovered by Buehler et al. [5]. Compared with other SMAs, Ni – Ti alloys can give a much larger deformation under the same conditions, have good chemical resistance and biocompatibility, and possess superior mechanical properties such as long fatigue life and relatively high ductility. Because of the large deformation occurring under a temperature variation, a SMA is an ideal material for a microactuator, especially for a microvalve.

Shape Memory Effects

In fact, not only alloys have shape memory properties, some polymers, ceramics and even biological systems also possess such properties. For example, bacteriophages can use the shape memory mechanism to enter into host cells. However, to date, only SMAs are widely used in microvalve fabrication. We will focus on the introduction of SMA microvalves.

Different from most normal materials, besides the shape changes resulted from elastic, plastic or thermal contributions, the SMA has three additional shape changes: a one-way effect shape change, a two-way effect shape change, and a pseudoelasticity shape change [6].

- One-way effect: the effect that the material remembers to return to its original shape when heated, but the material needs external loads to make it deform. This thermally driven deformation cycle is the basis for most SMA microvalves.
- Two-way effect: the effect that the material remembers two different shapes: one at low temperatures, and the other at high temperatures. In this situation, external loads are not necessary (intrinsic two-way effect). Normally, a SMA *remembers* its high-temperature shape and immediately *forgets* the low-temperature shape upon heating to recover the high-temperature shape. However, it can be *trained to remember* to leave some reminders of the deformed low-temperature condition in the high-temperature phase.
- Pseudoelasticity: the effect that the material does not need temperature variation to change its shape. It acts like a spring: expanding when added with a load and receding when released from an external load.

Key Research Findings

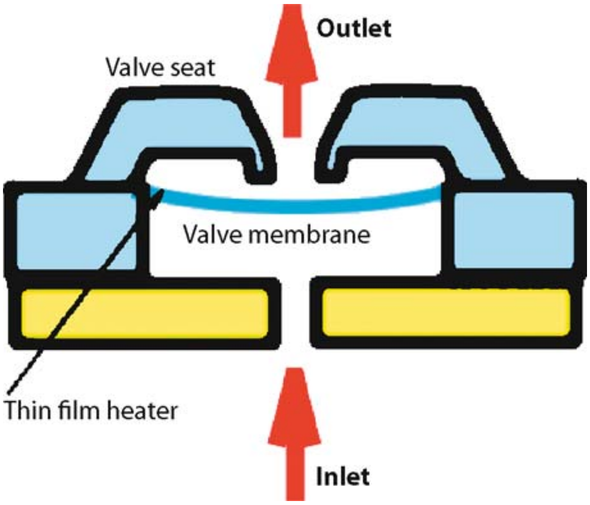
There have been too many studies and findings on thermomechanical microvalues to list all of them here. Some key research findings about the above-mentioned three cat-

egories of thermomechanical microvalves are briefly discussed here.

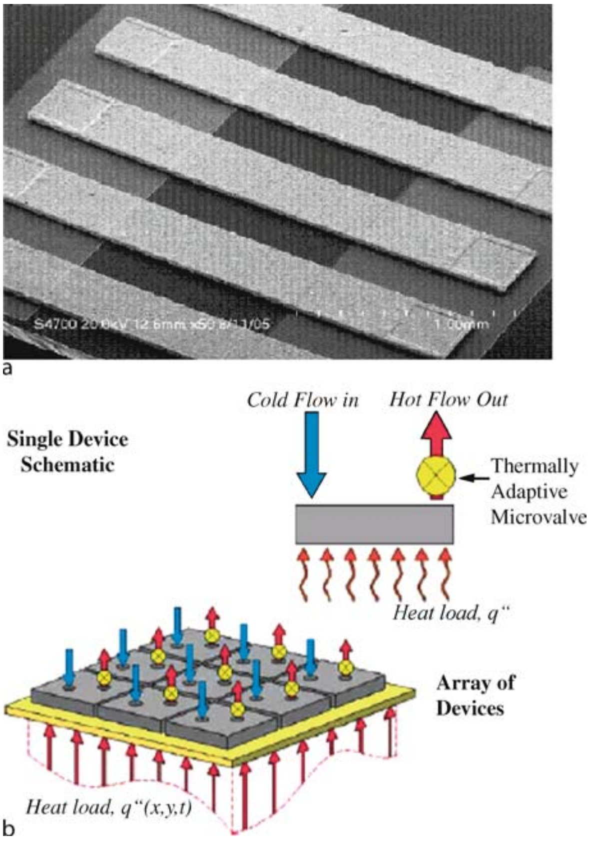
Thermal Expansion Microvalves

Thermal Expansion Buckling Microvalves

Figure 3 shows a basic setup of a normally closed thermal expansion microvalve. The main valve components usually include a valve seat, a valve membrane, a thin film polysilicon heater, an upper housing, and a lower housing. Generally, a thin film heater is used to heat the valve membrane. When the membrane is heated, the membrane begins to bulge allowing the flow to pass. A well-designed microvalve can possess a response time of about 10 – 20 ms, which is quite fast for a thermally driven microvalve. Most thermomechanical microvalves are active valves which use external thermal control to change the stage of the valve. A possible passive thermal buckling valve has been proposed [2] as shown in Fig. 4a. In contrast to active valves, passive valves utilize the properties of the fluid itself to control the stage of the valve. As shown in Fig. 4a, a clamped eccentric nickel beam is fabricated over a slot through the substrate. When the temperature is low, the gap between the beam and the seat is small, allowing a small mass of liquid to flow through it. But, if the temperature is high, the beam buckles, allowing a larger flow rate. These eccentric microbeams can potentially be used in the future for thermally adaptive microvalves which can self-regulate the flow. Figure 4b shows possible applications of these thermally adaptive microvalves. It illustrates the schematic of a MEMS skin-cooling scheme which is similar in nature



Thermomechanical Valves, Figure 3 A typical normally closed thermal expansion microvalve



Thermomechanical Valves, Figure 4 A passive thermal buckling valve. (**a**) Photograph of eccentric micro nickel beams; (**b**) application of the valve in MEMS adaptive cooling scheme for both a single device (upper) and an array of devices (bottom)

to the biological phenomenon of perspiration. When the temperature increases, the thermally adaptive microvalve can increase the flow of local cooling fluid, hence automatically enhancing the cooling strength. With this adaptive cooling strategy, the temperature of the surface can be well controlled under a spatially and temporally varying heating load.

SCE Microvalves

Figure 5a shows a schematic of a normally closed SCE microvalve which has been commercialized as the FluistorTM Microvalve of NC-105 by Redwood Microsystems. Different from the normally opened SCE microvalve, this microvalve has a fulcrum point on the flexible diaphragm. In its de-energized state, the body of the actuator falls down on the off-center orifice on the right and closes the flow. When heated, the trapped fluid expands to cause the flexible diaphragm to lever the body of the actuator away from the orifice and allow the flow to pass through. The Fluistor TM NC-105 has been reported to have a leak

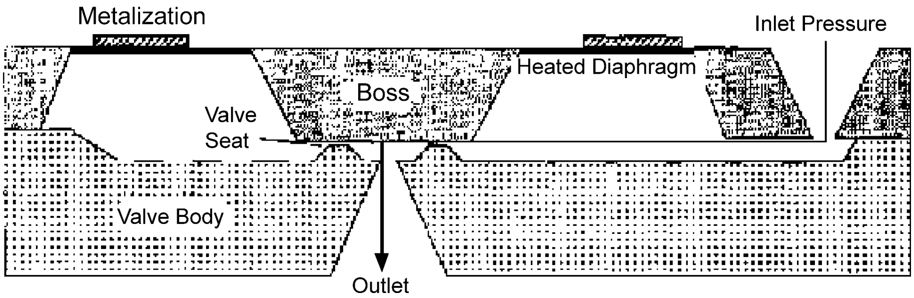
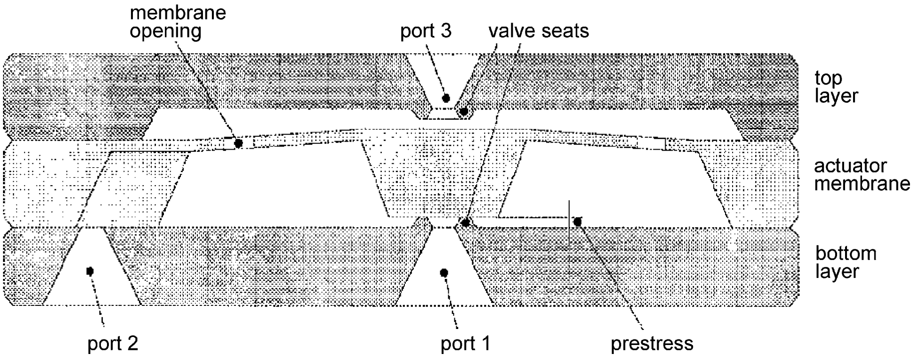
rate of no less than 0.006 ml/min of helium, which is acceptable in many applications. This valve cannot be used to control corrosive fluids, because it uses the flexible diaphragm to directly seal the valve and a very limited range of materials can be used to fabricate the diaphragm. This has since been improved by avoiding the use of the flexible membrane to directly seal the device. Figure 5b shows a typical Redwood Microsystems NC-1500-T normally closed valve, which works at an ambient temperature range of 0 – 55 °C and opens the flow at approximately 56 °C.

Besides the thermal expansion of the fluid and the volumetric expansion of the liquid–gas phase change, the expansion of the solid–liquid phase change can also be used in a SCE valve to actuate the action. Figure 6 shows the microvalve that Carlen and Mastrangelo proposed in 1999 [7]. This SCE microvalve is a normally opened SCE microvalve in which it uses the expansion of the solid–liquid phase change of the paraffin to actuate the switch. Figure 6a shows the schematic cross-section of the microvalve. Because paraffin has a large volumetric expansion upon melting, paraffin melts and expands 10 – 30 % when heated to 65 – 150 °C, and thus causes the flexible membrane to deflect vertically about 3 μm in 20 ms with a power requirement of less than 50 mW. The outward-flexing membrane will then come into good con-



Thermomechanical Valves, Figure 7 Schematic of a normally closed thermal bimorph-actuated valve



Thermomechanical Valves, Figure 8 Schematic of a bimetallically actuated three-way valve

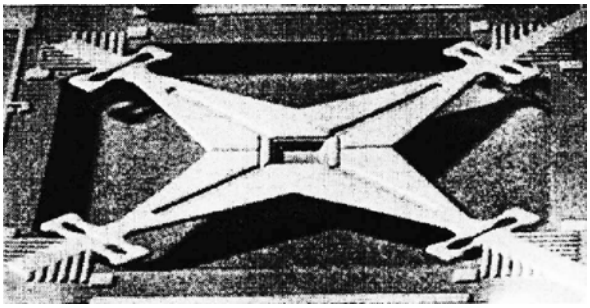
tact with the outlet hole above and cut off the flow. Figures 6b and 6c show, respectively, the top and bottom view of the SCE microvalve.

Bimetallic Microvalves

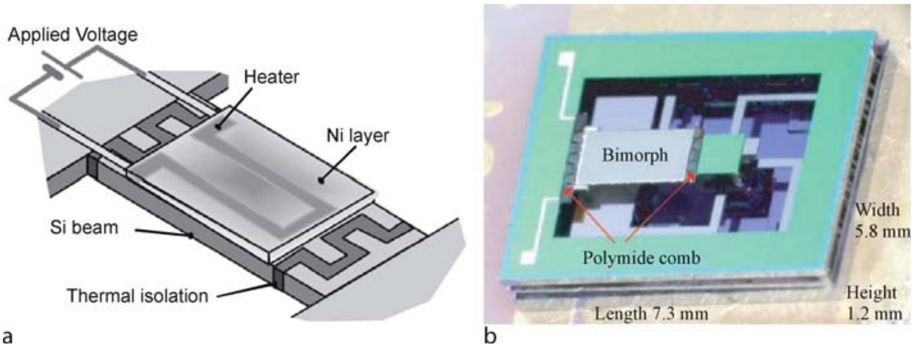
Classical Bimetallic Microvalves

In 1991, Jerman proposed a new microactuator based on a bimetallic membrane [8], which was later used to fabricate a normally opened microvalve and a normally closed microvalve. As shown in Fig. 7, a circular annular Al – Si bimetallic membrane with a central boss is used in the microvalve. The bimetallic diaphragm consists of a 5 μm-thick diaphragm of aluminum and a lower 8 μm-thick silicon diaphragm with embedded diffused resistors. In its de-energized state, the central boss seals the valve seat (400 μm × 80 μm) and thus closes the flow. When energized, the resistors heat the Al – Si bimetallic diaphragm making the central boss move up, thus allowing the flow. The displacement of the boss can be changed by altering the electrical power and the temperature of the diaphragm, which can be used to control the flow rate of the valve. The leakage rate of this valve is approximately 0.03 ml/min of nitrogen at a 34.5 kPa input pressure. This microvalve works well under the temperature range of −20 to +85 °C. The response time is about 150 ms, which is quite rapid for a thermally driven microvalve.

Figure 8 shows a similar bimetallic microvalve which was fabricated by Messner et al. [9]. In contrast to the microvalve shown in Fig. 7, it has another port (port 2) which is always open at the edge of the membrane. When the microvalve is de-energized, the center boss seals port 1 thus letting port 2 connect with port 3. When the boss is lifted by the thermally driven metallic membrane, port 1



Thermomechanical Valves, Figure 9 A four-leg bimetallic membrane microvalve



Thermomechanical Valves, Figure 10 A Si – Ni bimorph actuated microvalve with thermal isolation comb regions. (**a**) Thermal isolation comb regions; (**b**) photograph of the microvalve

is released and port 3 is sealed. Port 2 is connected with port 1. This 3-way microvalve is designed to control a differential pressure of 1000 kPa allowing a maximum flow rate of 800 ml/min for dry air at 600 kPa. The electrical power is about 1 W. It works properly in an ambient temperature range of 0 – 50 °C.

Power-Saving Bimetallic Microvalves

To minimize the thermal conduction loss from the membrane, Wang et al. [10] have proposed a new microvalve using a four-leg bimetallic *membrane*. Figure 9 shows their microvalve. In contrast to other bimetallic membrane microvalves, this microvalve has a four-leg Ni – Si bimetallic membrane at the center instead of an annular one. With less conjunction to the substrate this tapered-leg membrane largely decreases the thermal conduction loss, and thus significantly saves on the power required to actuate the valve. It has been reported that the power requirement of this design is 5.3 times less than that of the older design.

Tomonari et al. [11] have used thermal isolation comb regions to minimize the thermal conduction loss from the membrane in their microvalve. As shown in Fig. 10a, they used a Si – Ni bimorph as the microactuator. They fabricated thermal isolation comb regions on either side of the silicon bimorph by etching Si and filling the structure with polyimide resin. Because of the low heat conductivity of the polyimide resin, this structure can effectively protect from heat loss. Figure 10b shows their microvalve.

Other Attempts to Switch the Flow Using Bimetallic Structures

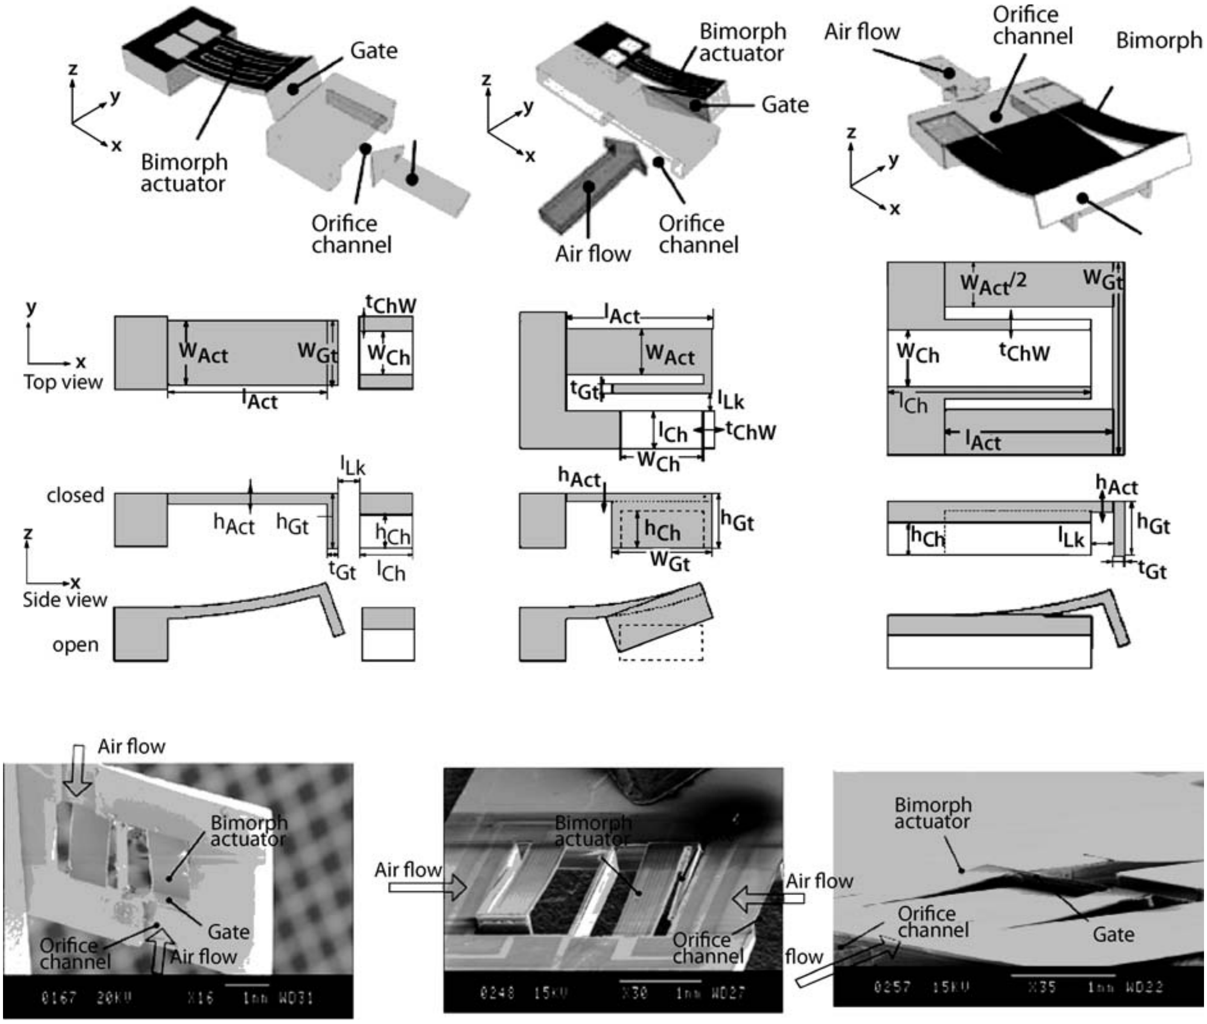
Many other attempts to switch the flow using bimetallic structures have been made. Walters et al. [12]. introduced gate microvalves (cross-flow microvalve or X-microvalve) in 1998. In a gate microvalve, the valve gate moves perpendicular to the flow and static pneumatic force. Figure 11 shows the bimorph-actuated gate microvalves reported by Haasl et al. [13]. The shortcoming of these microvalves is that leakage is unavoidable in the closed state because the limited actuation energy in microsystems does not allow friction between sliding structures.

In 1992, Doring proposed using the bimetallic microcantilever structure to direct a fluid jet. Later, on the basis of this idea, Trah et al. [14] fabricated a micromachined normally closed valve using an Al – Si cantilever, as shown in Fig. 12. When the cantilever is in its de-energized state, the cantilever is slightly bent upwards and directs the fluid to the room above the membrane. Thus, the pressure in the upper room is a little larger than that in the lower room. The pressure difference presses the boss down to the valve seat and seals the valve. When the cantilever is heated and thus bends downwards, the fluid jet also deflects downwards and flows into the lower room to lift up the boss. Thus, the valve opens. The size of the valve is 14.5 mm × 8.5 mm × 1.43 mm. The valve was designed to control a flow rate of 75 ml/min at time constants of about 0.5 ms.

Thermally Driven SMA Microvalves

Microvalves Using Sputtered SMA Thin Films or Rolled Sheets

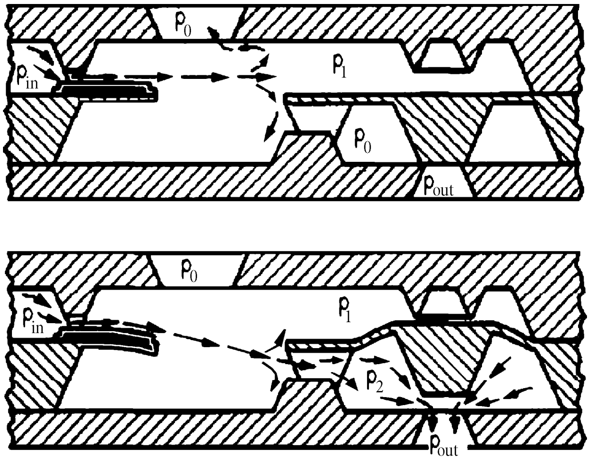
Thin films and rolled sheets are the most widely used format in microvalve fabrication. Usually a SMA microvalve consists of an upper and a lower housing integrated with a valve seat and fluidic connections, a membrane, a spacer, and a SMA microactuator. The deformation actuated by the SMA thin film pushes or pulls the spacer to seal or open the valve seat, thus to close or allow the liquid to flow through the valve seat.



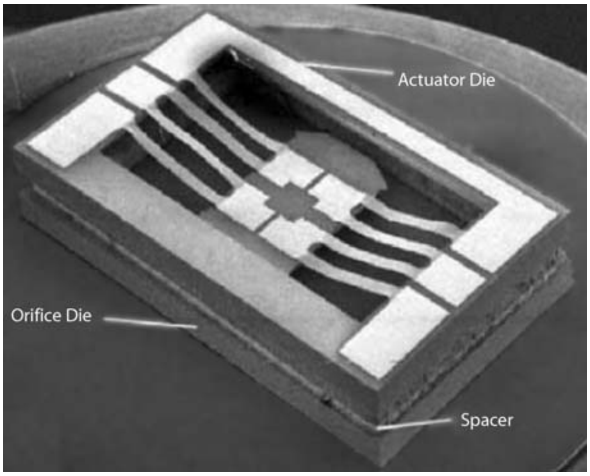
Thermomechanical Valves, Figure 11 Bimetallically actuated gate microvalves

The method of using SMA films to fabricate microvalves can be traced back to Busch and Johnson [15] who successfully fabricated a Ni – Ti film using sputter deposition and crystallization processing techniques and also suggested some microvalve and micromirror structures. Because a Ni – Ti thin film can generate 10 J per cubic centimeter per cycle, it can be used as a heating resistor, which can largely simplify the structure because it avoids the use of additional heaters. They later developed a normally closed SMA microvalve where a Be – Cu spring was used to push a sapphire ball against the silicon over the spacer to close the flow orifice in a de-energized state, as shown in Fig. 13. A thin Ni – Ti SMA film is deposited onto a silicon substrate and is cut into the shape of microribbon by using the photolithography and selective etching techniques. When heated, the Ni – Ti microribbons return to the original undeflected state to move the silicon back from the orifice and thus open the microvalve.

There have been further developments in microvalves using sputtered SMA thin films. The major research efforts have been concentrated on the optimization of the SMA film shape through the simulation of the stress distribution in the film. Figure 14 shows a stress-optimized SMA microdevice designed by Skrobanek et al. [16]. The goal of this practice is to ensure that the stress values in the thin film should be sufficiently high to provide large work outputs, and low enough to avoid fatigue effects. Ikuta et al. [17] have fabricated fluid-driven chips containing multiple pumps and switching valves for the biochemical IC family. The switching valve that they fabricated was driven by a SMA film. Figure 15 shows the operating principle of their switching valve. In contrast to normal valves, this valve has two outlets instead of one. Due



Thermomechanical Valves, Figure 12 Schematic and principle of a hydraulic actuated microvalve

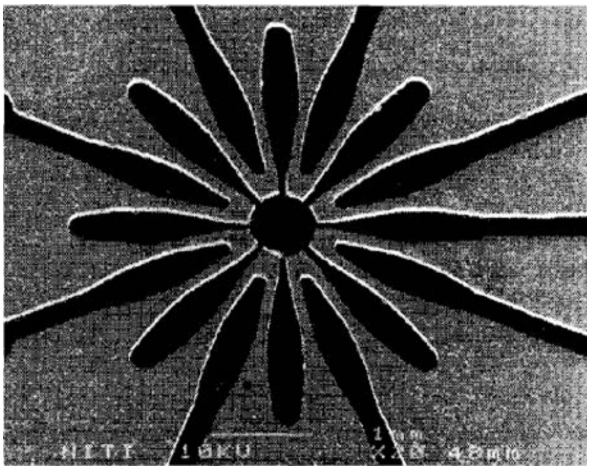


Thermomechanical Valves, Figure 13 SMA microvalve

to the lever action of the silicon rubber, when the SMA actuator pushes the spacer down to seal the right outlet 2, it opens the left outlet 1 automatically. The switching time in the active (heating) phase is 0.5 s and the response time of the opposite way in the passive (cooling) phase is about 2 s. Different Ni – Ti – x alloys were also tried to fabricate such microvalves. The use of Ni – Ti – Pd alloys provides a higher ambient temperature application, and Ni – Ti – Cu alloys provide a higher recoverable stress as compared to Ni – Ti alloys.

Microvalves Using SMA Wires

Micropinch Valves Using SMA Wires SMA wire is commonly used in micropinch valves. A micropinch valve usually consists of a soft tube and a SMA wire. The SMA

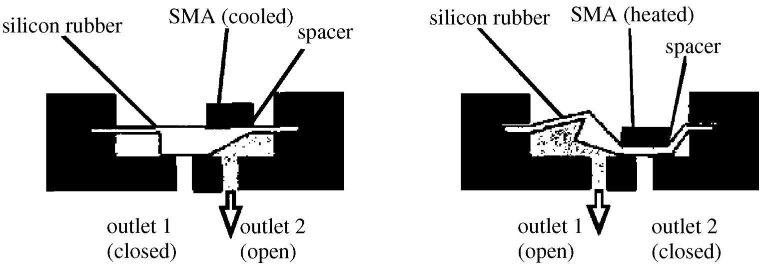


Thermomechanical Valves, Figure 14 Stress-optimized microdevice

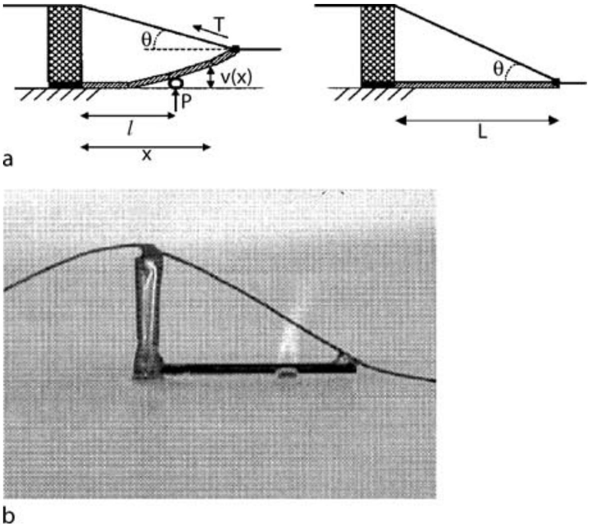
wire pinches the tube to close the flow and releases it to open the flow. The first pinch valve using a SMA wire was used in an implantable drug delivery system [18]. A 120 μm-diameter Ni – Ti wire was used to pinch down a silicone rubber tube with an inner diameter of 0.6 mm and an outer diameter of 1 mm. This value is operated with a pressure difference of 200 kPa and can open in less than 1 s with a power consumption of 120 mW.

Later, more normally closed pinch valves were developed. Figure 16 shows another normally closed pinch valve developed by Pemble and Towe [19]. The valve consists of an actuator and silicon tubing. The actuator consists of a 152 μm-diameter Ni – Ti contraction wire in tension with a 584 μm-diameter Ni – Ti superelastic wire. One end of the actuator is fixed to a flat surface using epoxy. In the de-energized state, the actuator tightens the tube and makes it deform to block the flow. When the contraction wire is electrified, Joule heating causes the superelastic cantilever to bend upward. This upward deflection relieves pinch pressure on the tubing thereby allowing the flow. In this pinch valve, the outer diameter of the silicone tubing is 1.2 mm and the inner diameter is 0.64 mm. It operates with a pressure difference of 20.7 kPa and a flowrate of up to 48 ml/min at a current of 420 mA. The valve can be opened in less than 1 s and then closed in less than 2.5 s. The calculated power dissipation has been reported to be 398 mW.

Figure 17 shows a relatively economical micropinch valve fabricated by Piccini and Towe [20]. The system consists of a microbore silicone tube, a Ni – Ti SMA wire, a miniaturized synthetic ruby ball and a thermocouple. All of the components are off-the-shelf components. As shown in Fig. 17, the ruby ball blocks the tubing in a nor-



Thermomechanical Valves, Figure 15 Schematic of a SMA switching valve



Thermomechanical Valves, Figure 16 SMA pinch valve. (**a**) Schematic of the valve; (**b**) photograph of the valve

mal state. When electrified, due to Joule heating, the SMA wire stretches the microbore silicone tubing away from the ruby ball and the gap between them allows the flow. This microvalve has been reported to have a response time of 2.5 s with a power pulse of 213 mW.

Other Microvalves Using SMA Wires Figure 18 shows another type of gate microvalve using SMA wires [21]. A paddle suspended from a silicon beam is placed on the valve seat. In its de-energized state, the hole in the paddle fits in with the valve seat and allows the flow. When electrified, the SMA wire is heated by Joule heating and bends to push the paddle aside from the valve seat and closes the inlet opening. When the SMA wire cools down, the paddle is pushed back by the silicon beam to allow the flow again.

Future Directions for Research

Various thermomechanical microvalves have been developed with the development of MEMS fabrication technology. Thermomechanical microvalves work by converting thermal energy into mechanical deformation. Compared with other microvalves, such as magnetic microvalves, electrostatic microvalves, and piezoelectric microvalves, thermally driven microvalves have their own advantages such as simplicity of fabrication, controllable deflection (by adjusting the input power), and a relatively large actuation force.

However, thermally driven microvalves also have their drawbacks. First, they have a relatively long response time. Second, because heat dissipation is unavoidable, more attention must be paid when designing a microvalve. In most circumstances, heat dissipation in a thermally driven microvalve is a trade-off. For example, a small heat dissipation helps to obtain a high heating rate to open the valve; while at the same time it also means a low cooling rate to close it. Third, the performance of a thermally driven microvalve is largely affected by the ambient temperature. A thermally driven microvalve usually works within a relatively small temperature range. Fourth, compared to the heating process, the cooling process is relatively difficult to achieve. The cooling process is always the bottleneck in reducing the response time of a thermally driven microvalve. Generally speaking, the response time of a thermally driven microvalve is of the order of a second. Fifth, sometimes due to the large power consumption, a thermally driven microvalve is not appropriate when the energy consumption is limited. Sixth, thermal expansion may cause loosening to the support which may introduce some leakage problems. Seventh, the closing time may not be the same as the opening time. Finally, heating of the fluid may not be appropriate in some MEMS applications because it may introduce some local boiling on the electrode.

Thermomechanical Valves, Figure 18 A gate microvalve acuated by a SMA wire at (**a**) open position; (**b**) closed position

Overcoming the shortcomings of the thermomechanical microvalves listed above will be the main tasks for future studies in this area. The development of new materials and exploring new methods to make thermomechanical microvalves will also be promising directions.

Definitions

Thermophoresis is defined as the migration of a colloidal particle or large molecule in a solution in response to a macroscopic temperature gradient. The inverse effect, i. e., the formation of a temperature gradient as the result of the mixing of different molecular species, is referred to as the *Dufour effect*. The ►Soret coefficient is defined as the ratio of the thermal diffusion coefficient and the normal diffusion coefficient; it is a measure for the degree of separation of the species. These concepts are the same as for a molecular mixture.

Physical Principles

A colloidal particle or large molecule can be driven to move in a gas or a liquid by the application of a non-uniform temperature field. The mass flow rate $\boldsymbol{J}_\mathrm{m}$ of a species or of colloidal particles as the result of a thermal gradient ∇T in a fluid is given in, e. g. [1]:

$$\boldsymbol{J}_\mathrm{m} = -\rho D \nabla c - \rho D_\mathrm{T} c(1-c)\nabla T\,, \tag{1}$$

where ρ is the fluid density, D the diffusion coefficient, D_T the thermal diffusion coefficient, and c the species or particle concentration in terms of mass fraction. The first term on the right hand side is the Fick diffusion law, while the second term describes the migration due to the thermal gradient.

In a stationary state the mass flux vanishes (i. e., $\boldsymbol{J}_\mathrm{m} = 0$), and the Soret coefficient S_T is given by [5]:

$$S_\mathrm{T} \equiv \frac{D_\mathrm{T}}{D} = -\frac{1}{c\,(1-c)}\frac{\nabla c}{\nabla T}\,. \tag{2}$$

Hence, the effectiveness of the separation is given by the Soret coefficient, while the rate of separation is determined by the diffusivity. In general the thermal diffusion coefficient D_T is a function of temperature and concentration, which complicates the description of thermophoresis.
Thermophoresis as defined above occurs in liquids. For molecular mixtures of gases there is a sound theoretical description [5], but a theory has not been formulated satisfactorily for liquids.

Key Research Findings

For gases thermophoresis can be described using Chapman–Enskog theory [5], assuming a Maxwell–Boltzmann distribution for the velocity of the molecules, with corrections. This approach is only valid when the relative temperature change over the molecular free path is small. Using Onsager's theorem the transport equation can be derived from the entropy production, which is described by De Groot [5].
For liquids there does not yet exist a satisfactory theoretical description, despite more than 150 years of research since the first description of thermophoresis by Ludwig [6] and Soret [7]. Theoretical descriptions fail to predict correct values of the Soret coefficient, and sometimes even fail to predict the correct sign. Hence, thermophoresis remains an area of active research, both on a theoretical and practical level. Below follows an overview of approaches applicable to large molecules or colloidal particles in suspension.

Thermophoresis of a Particle with a Thin Diffusive Layer

Ruckenstein [8] proposed that thermophoresis, diffusiophoresis and electrophoresis can be described as the result of a variation of the surface tension (due to a variation in the surface potential; see Fig. 1), so that the motion of a particle is analogous to the Marangoni effect, i. e.:

$$U_\mathrm{T} = -\frac{\varepsilon\varsigma^2}{32\pi\eta}\frac{\mathrm{d}\ln T}{\mathrm{d}z} \equiv -\frac{\ell}{\eta}\frac{\mathrm{d}\gamma}{\mathrm{d}T}\frac{\mathrm{d}T}{\mathrm{d}z}\,, \tag{3}$$

where $\ell = \chi^{-1}$ is the Debye length (i. e., the thickness of the diffusive layer), η the dynamic viscosity of the fluid, ς the surface potential, and $\gamma = \gamma_0 - \frac{1}{8\pi}\varepsilon\chi\varsigma^2$ is the interfacial tension (where the second term on the right is related to the total free energy of formation of the diffusive layer) [8].

Hydrodynamic Models

Brenner [9] proposes a different description of fluid dynamics. He proposes that $\nabla \boldsymbol{v}$ in Newton's rheological law should not be based on the mass based velocity of the fluid, but on its 'volume velocity.' This is a controversial idea. The adapted Navier–Stokes equations provide a hydrodynamic description of thermophoresis and thermal creep. Bedeaux et al. [13] describe how this alternative approach of the transport equations can be validated experimentally by means of thermophoresis.

It would go too far to derive the complete set of equations here so we suffice with the thermophoretic velocity given by Brenner [9]. The thermophoretic velocity U of a sphere is:

$$U = -\frac{\alpha\beta}{1 + k_p/2k}\nabla T\,, \tag{4}$$

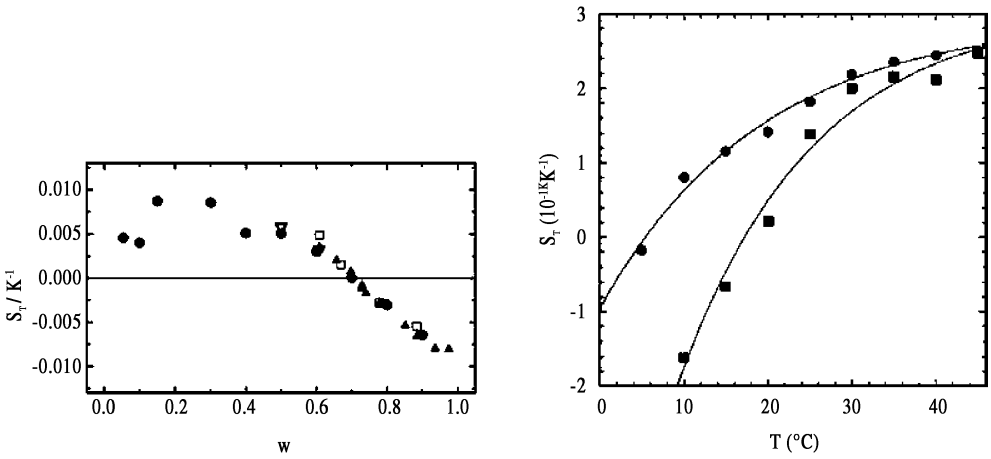
where α is the thermal diffusivity, β the thermal expansion, and k and k_p the thermal conductivity of the solvent and particle respectively.

Solvent Particle Interactions

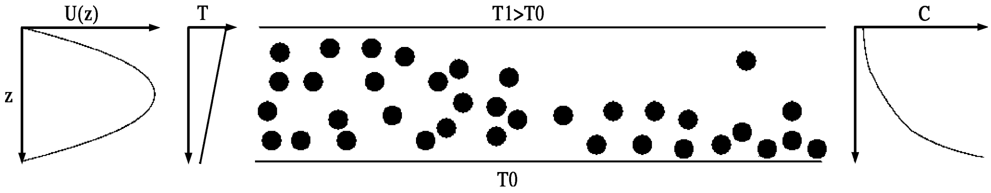
The entropy of particle solvent interactions plays an important role in thermophoresis. The description by [5] of thermophoresis in gases is based on entropy. In complex fluids the entropy of the interaction between molecules or particles and solvent leads to thermophoretic motion. Schimpf & Semenov [10] consider the slip flow caused by a local pressure gradient set up by the temperature dependent properties of the particle and solvent. They find the same thermal expansion proportionality factor as Brenner [9] who does not consider these interactions.

Change of Sign of Soret Coefficient

The Soret coefficient is not a constant; it may vary due to changes in concentration or temperature. A positive Soret coefficient means a thermophobic particle. The Soret coefficient can change sign as a function of concentration [1] or temperature [3] (see Fig. 2). The inversion temperature for latex particles, which only have electrostatic interactions with water, lies close to the maximum density of the solvent at 4 °C. Iacopini et al. [3] conclude based on empirical findings that the thermal expansivity is the major factor in thermophoresis. They claim that this effect can be added to the Soret coefficient caused by the entropy production of particle solvent interactions. The similarity between the results of Brenner [9] and Schimpf & Semenov [10] suggests that this may be valid. For molecular mixtures, Haase [14], Kempers [15] and Rousseau et al. [16], have given important contributions.



Thermophoresis, Figure 2 Inversion of the Soret coefficient. Left: Soret coefficient measurement of water ethanol mixtures, compiled from results obtained by different groups, which shows an inversion of the Soret coefficient for increasing ethanol weight fraction (from Wiegand [1]). Right: Soret coefficient measurement of latex particles (circles) and pMD31 DNA (squares), which shows an inversion of the Soret coefficient with decreasing temperature (from Iacopini et al. [3])



Thermophoresis, Figure 3 Thermophoresis of particles in a microchannel. The top wall has a higher temperature and repulses the particles for thermophobic particles (i. e., a positive Soret coefficient). An exponential concentration profile is established at the channel outlet

Examples of Application

Thermophoresis is applied in industry for the separation of (large) molecules or small particles from their solvent in so-called *thermal field flow fractioning* (TFFF) [11]. A down-scaled version of this process to microscopic scales demonstrated thermophoretic separation on microscopic scales [4, 12]. The advantage of using the very small confinement in a microfluidic device is that the separation times can be reduced, so that thermophoretic separation can be used. Braun & Libchaber [2] use a combination of thermophoresis and convection to concentrate DNA samples. The disadvantage of this approach is that it is a batch process.

As an example we estimate the timescales required to continuously separate a species in a microchannel (see Fig. 3). Consider a two-dimensional channel, e. g., a fluid between two parallel plates separated by a distance h. For low concentrations (i. e., $c \ll 1$) one finds the following stationary solution (i. e., $\boldsymbol{J}_\mathrm{m} = 0$) for the concentration:

$$c = c_0 \exp\left[-S_\mathrm{T}(T - T_0)\right] \qquad (5)$$

where c_0 and T_0 are a reference concentration and temperature respectively. The effectiveness of the separation is essentially given by the Soret coefficient. The time scale τ to reach the steady state is given by:

$$\tau = \frac{h^2}{\pi^2 D} \,. \qquad (6)$$

For a colloidal particle with a diameter d that is suspended in a fluid with a dynamic viscosity η, the diffusion constant is given by:

$$D = \frac{kT}{3\pi \eta d} \,, \qquad (7)$$

where k is the Boltzmann constant ($k = 1.38 \times 10^{-23}$ J/K). A typical particle diffusion coefficient is $D \sim 0.9 \times 10^{-12}\ \mathrm{m}^2/\mathrm{s}$ (e. g., $T \sim 300$ K, $\eta \sim 10^{-3}$Pa s, $d \sim 490$ nm). For a micro-channel (with a typical channel width of $h \sim 10 - 100$ µm) the time scale τ is typically of the order of $10 - 10^3$ seconds. This means that one has to use long microchannels in combination with low flow rates to establish a high separation ratio.

Another advantage of implementing thermophoretic separation at a microscopic scale is that one can reach very large temperature gradients without applying large temperature differences. For example, a 5 K temperature difference over a 50 μm channel implies a temperature gradient of $\sim 10^5$ K/m, while the absolute variation of temperature is limited. This is beneficial in the case of biological samples (cells, proteins, DNA) where large variations in temperature can disintegrate the samples. However, the difficulty lies in establishing and maintaining a temperature difference in a microfluidic device, which is complicated by the high conductivity and small dimensions at small scales. A design of a microfluidic device for thermophoretic separation is given by Geelhoed et al. [4].

Thermopneumatic membrane valve

Definition

A thermopneumatic valve is a type of micromachined active valve operated by the volumetric thermal expansion of a heated gas or heated liquid in a sealed chamber [1].

Overview

The rapid development of new methods of fabrication and microfluidic components enables the desired control and manipulation of small amounts of fluids. The microvalves in microelectromechanical systems (MEMS) are essential elements of a micro total analysis system. Typically, there are two types of microvalve: one is the passive valve the operation of which is dependent upon its surrounding pressure conditions; the other is the active valve, which can be controlled actively. Active valves are categorized in three major ways: initial working state, control pattern, and actuation principle. Each microvalve has advantages and disadvantages from the viewpoint of power consumption, integration method, response time, operation frequency and voltage, fabrication process, and actuation efficiency. Among the various types of microvalves, thermopneumatic actuation provides a large achievable volume stroke and simple fabrication process relative to other actuation methods for microvalves [1].

A thermopneumatic valve typically consists of a moveable valve diaphragm, a valve seat, and a resistive heater in a sealed cavity. While electrical power is applied to the resistive heater, the initial volume of gas in the sealed chamber expands. Using the volumetric change of the heated gas in the cavity, the diaphragm structure

is deformed and subsequently blocks the fluidic path. Heated effluents (in liquid form) can also be used for thermopneumatic actuation using the phase transition to gas [2, 3]. A thermopneumatic microvalve can be fabricated with rigid materials such as silicon, metal, and glass. The silicon-based valve devices often face issues such as reliability (cycles or time to failure), wear/tear, residual stress, and high production cost. The residual stress is one of the major issues in MEMS devices. As shown in Fig. 1 [4], a corrugated structure can be used for minimizing the process-dependent residual stress of boron-doped silicon film [5]. Its effectiveness is verified experimentally through comparison between the static deflection characteristics of flat and corrugated diaphragms (Fig. 2) [4]. The development of the soft-lithography process [6, 7] allows the rapid prototyping of microfluidics devices. Elastomers possess outstanding mechanical and optical properties, which can provide effective solutions to overcome the limitations of silicon-based microvalves. By choosing elastomers as valve materials, several issues such as valve efficiency, capacity, power consumption, response time, leakage, closing force, biocompatibility, and biochemical compatibility can be addressed. These can also allow the large-format integration of thermopneumatic microvalves with a thin PDMS membrane [8]. For more reliable operation of thermopneumatic microvalves, Parylene C (i. e. gas-impermeable layer) can be deposited on PDMS (i. e. non-porous rubbery elastomer with high gas permeability).

Hot wire; Hot film

Definition

A *thermoresistive flow sensor* refers to the flow measurement element based on monitoring the thermal states of an electrically heated sensor whose dependence on the heat loss represents the flow rates of the surrounding fluid. The thermoresistivity of a sensor reflects its variation in electrical resistivity with temperature. A sensor element should usually have a sufficiently high temperature coefficient of resistance (TCR). Typical sensor materials are platinum, nickel, or polysilicon with a specific TCR in the order $\sim 10^{-3}$ °C. The highest measured resolution for the latest thermoresistive flow sensors has reached the order of $\sim$ nl/min.

Overview

Most commonly used microflow sensors are based on thermal principles [1]. Owing to its superior simplicity, which allows it to be integrated in a MEMS device, the thermoresistive flow sensor has been widely adopted in a variety of practical situations such as: biomedical and home applications, environmental monitoring, process control, microanalysis systems etc. [2, 3]. The dependence on the heat loss between a fine wire or thin film, which serves as the sensor, and the surrounding fluid has traditionally been among the most accepted methods for measuring fluid flow [4]. A thermoresistive flow sensor refers to the flow measurement element based on monitoring the thermal states of an electrically heated sensor immersed in or besides the flowing fluid medium such as a gas or liquid [5]. It usually works when the other physical properties of the fluid such as temperature, composition, density, and pressure are constant, therefore the only variable which affects the heat transfer of the sensor is the flow rate.

A microthermoresistive flow sensor can be composed of a variety of combinations of heat sources and temperature sensors. It typically consists of a heater and one or more temperature sensors [1, 6]. Up to now, thermistor principles, geometries, and sensor materials have been found in a wide variety of combinations from CMOS compatible thermocouples to thermistors with different material compositions and geometries, from bridge structures to membranes [6]. The fluid (a gas or liquid) can either flow over the entire chip or over a controlled area of the chip through an integrated microchannel [2]. The flow rate is estimated by measuring the heating power, heater temperature, fluid temperature, and the time-of-flight of a heat pulse.

The electrical resistance of a thermoresistive flow sensor can be calibrated as a change in the temperature. A linear relation between them is usually adopted, i. e.

$$R(T) = R(T_0)\left[1 + \alpha (T - T_0)\right] \tag{1}$$

where $R(T)$ is the sensor resistance at operating temperature T; $R(T_0)$ is the sensor resistance at the reference temperature T_0; α is the temperature coefficient of resistance, which includes the effects of lead and wire resistance change and may depend on a reference temperature. When an electrical current I_0 is applied on a thermoresistive flow sensor and its self-Joule heating is maintained at a constant level, any fluid flow through the sensor will cause a shift in its temperature and thus resistance R, respectively. As a result, a decrease in the voltage V $(= I_0 R)$ of the sensor will be detected. The aim of the thermoresistive flow sensor is to evaluate such changes caused by variations of the flow rate alone.

The most typical electrical circuits for control and evaluation of a thermoresistive flow sensor are based on the well-known Wheatstone bridge using either the constant-current or the constant-temperature mode, respectively [4]. In a constant-current circuit (see Fig. 1a), resistors R_3 and R_4 at the two arms are much larger than the sensor resistor R_1. Therefore, the electrical current through R_1 is essentially independent of the changes in the sensor resistor R_1. Any flow in the channel cools the hot wire, decreases its resistance as given by Eq. (1), and unbalances the bridge, which then produces an output voltage V. The voltage V is generally small and must be amplified before it is recorded [4]. The values of the TCR α for R_1 and the variable resistor R_2 should be equal in order to eliminate any signal errors due to changes in the ambient temperature. The values of TCR for R_3 and R_4 should also be equal.

A constant-temperature Wheatstone bridge is shown in Fig. 1b. The circuit bridge is balanced in advance under noflow conditions using the variable resistor R_2. Therefore with the flow of the fluid, the hot wire or film is cooled and its resistance decreases and unbalances the bridge. A differential amplifier would then balance the bridge with a feedback voltage [4]. Such electrical output correlates directly with the flow rate.

Traditionally the thermoresistive flow sensor appears as a wire or film embedded inside the flow field. In a microfluidics-related measurement, the microthermal sensor is usually mounted in the wall of a microchannel to avoid disturbing the flow and thus accurately measure the fluid. Due to the highly confined geometry, a complicated MEMS technique has to be adopted for the fabrication of the thermoresistive flow sensor. At present, most of the commercially available sensors are usually inadequate for precise flow control in microfluidics because of their limited sensitivity, large size, high dead volume, and difficulties in interfacing with microfluidic devices [7]. Miniaturization of a sensor in micro- or nanoflow is therefore a necessity, since only a small size will allow for a precise, local and high transient resolution in temperature measure-

ment, power reduction, and integration with devices [6]. Overall, the microthermoresistive flow sensor relies heavily on miniaturization and innovation of different well-established thermal macroflow sensing principles. There are three main types of thermal flow sensor which combine the evaluation methods and heater modes: hot-wire (hot-film), calorimetric, and time-of-flight [1]. Each of these sensors types can be further categorized according to their thermal sensing principle as: thermoresistive, thermocapacitive, thermoelectric, thermoelectronic, or pyroelectic. Only the thermoresistive flow sensor will be illustrated in this essay. To interpret the mechanisms of using such sensors to measure the flow parameters, typical principles, and practical design of the device will be considered. Some fundamental issues which will require further investigation are noted.

Basic Methodology

Principle

The operating modes for the microthermoresistive flow sensor are similar to their conventional bulk ones. For traditional research applications, cylindrical sensors which take the form of either a fine wire (typical diameters of 1 – 15 μm) or a cylindrical film (typical diameters of 25 – 150 μm) are the most common. The wire sensor is mainly used for clean air or gas measurement due to its fragility, while hot-film sensors can be used in both liquid and contaminated-gas environments [4]. A major difference between a microthermoresistive flow sensor and its traditional counterpart is that, the former has to be made using micro- or nanofabrication technologies such as bulk micromachining, surface micromachining, epimicromachining, and LIGA-techniques, etc. These new sensors have been able to measure very small flows in the nanoliter and microliter ranges. Depending on the location of the heating and sensing elements, the flow sensors can be either intrusive (lying in the fluid), or nonintrusive (located outside the flow). The intrusive type has many limitations such as disturbing the fluid, easy corrosion or damage, and difficulty in integrating with the channel [4]. Thus, it is more common for nonintrusive thermal sensors to be used in micro- or nanofluidics. The sensors are often embedded in the wall of a microchannel for flow measurement.

The three existing types of thermoresistive flow sensor are generally classified as hot-film, calorimetric, and time-of-flight type, respectively. The basic operating principle of a hot-film flow sensor is based on microconvective heat transfer from a heated thin-film sensing element (also called a heater) to a liquid flowing inside a microchannel [7]. When the sensor (heater) is subjected to a constant current heating, forced convection by the flow causes a decrease in the heater temperature. The flow rate of the fluid can be identified by detecting the effect of the flowing fluid to the sensor. Figure 2a illustrates the geometric design of such an MEMS flow sensor and its operating principle. Here, the heater is built on the wall of the microchannel. By detecting the sensor temperature, one can obtain the liquid flow rate using a precalibrated experimental curve for temperature versus flow rate (see Fig. 2b). In terms of the calorimetric principle, a widely used microthermoresistive flow sensor is the ►thermal anemometer, which typically consists of a middle heater with an upstream and downstream temperature sensors, relative to the flow direction [2]. Such a calorimetric sensor is based on measuring the asymmetry temperature profile around the heater, modulated by the fluid flow [1, 8]. The schematic representation of a calorimetric device and the temperature distribution in the flow direction are shown in Fig. 3. The MEMS flow sensor consists of three electrical resistors which are mounted directly onto the substrate at the bottom of the fluidic channels. The heating element is located in the middle of the flow channel and is symmetrically encircled by two sensor elements. This symmetric arrangement makes the sensor insensitive to fluctuations in the ambient temperature and enables the flow direction to be detected. The resulting temperature gradient is detected by the two ►temperature sensitive resistors. At zero flow rate, no convection exists in the channel and the heat generated will be transmitted by diffusion. As

T

Thermoresistive Flow Sensors, Figure 3 Schematic diagram for calorimetric principle: (**a**) flow microsensors: (**b**) temperature distribution for flow measurements. Modified from [7]

the temperature distribution surrounding the heater is symmetric, no temperature difference is detectable (see Fig. 3). The diffusion can be split into two contributions: the diffusion through the substrate, and that into the fluid via the upstream and downstream directions. Due to heat dissipation, the temperature change is reduced, and may be lower than the detection limit [9]. An increase in the flow velocity shifts the temperature maximum into the direction of the flow. The flow measurement is therefore achieved by the temperature difference between the downstream and upstream sensor microfilaments, whose correlation with the flow rate can also be precalibrated.

The flow measurement principle for the time-of-flight sensor is illustrated in Fig. 4. In this method, the time taken for a heat pulse to pass over a known distance is recorded. The heat pulse generated by an electrical pulse applied to the heater microfilm travels due to the fluid flow and is detected by a sensor microfilm [8, 10]. The time between the heat pulse generation and its detection can then be used for flow estimation (Fig. 4b).

In each of the above thermoresistive flow sensors, the sensor elements are powered by an electrical current like that shown in Fig. 1. The electrical components used for the heater can operate either in a constant heating temperature or in a constant heating current mode depending on whether or not a feedback loop circuit is adopted [1, 2, 5]. The former usually has a fast response. In order to detect the differential voltage, a specific test circuit needs to be manufactured on the device in advance.

Sensitivity of Thermoresistive Flow Sensor

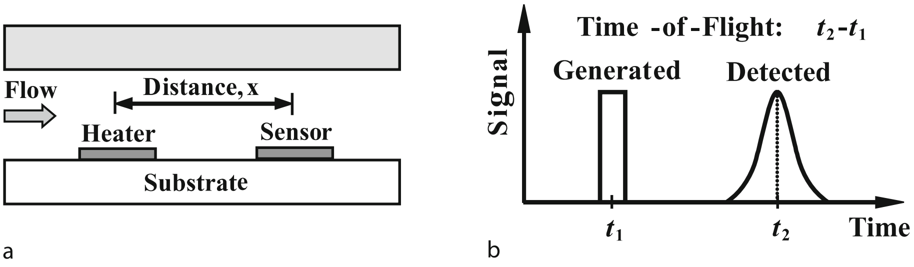
The highest flow measurement resolution for a thermoresistive flow sensor has been in the order of nano- or microliters. To illustrate the basic method of characterizing the sensitivity of a thermoresistive flow sensor, we consider here only a single sensor element for a Lab-on-Chip application, i. e., the hot-film case. For a single thermoresistive element, it utilizes a miniaturized adaption of the anemometric principle. The combination of an established detection principle with the benefits of microtechnology has resulted in a sensor with very high sensitivity [9].

Electrically, the flow-induced output voltage change for the circuit such as shown in Fig. 1a can be written as [7]

$$\Delta V = I_0\left[R(T) - R(T_0)\right] = V_0 \alpha \Delta T \tag{2}$$

where I_0 is the constant current, $V_0 = I_0 R(T_0)$, $\Delta T = T - T_0$.

If the sensitivity (S_V) of a sensor is defined as the ratio between the changes in the sensor output voltage and flow



Thermoresistive Flow Sensors, Figure 4 Flow measurement by time of-flight principle. (**a**) Sensor configuration; (**b**) Sensor signal. Modified from [7, 9]

rate (Q), i. e., $S_V = \Delta V/\Delta Q$, one has

$$S_V = V_0 \alpha \frac{\Delta T}{\Delta Q} = V_0 \alpha S_T \tag{3}$$

where $S_T = \Delta T/\Delta Q$, represents the temperature–flow ratio, and is related to the sensor structure design and fluid properties. The sensitivity can be assessed in an average sense by the slope of a straight line fitted to the measurement data. In the microflow measurement, if the temperature variation of the sensor is recorded, the flow rate of the fluid can then be estimated through curve fitting.

Further, S_V may involve an original bias voltage that is not related to the sensor design. Thus, it is more appropriate to normalize the sensitivity by the initial bias signal and define the relative sensitivity as [7]

$$S_{V/V_0} = \frac{\Delta V/V_0}{\Delta Q} = \alpha \frac{\Delta T}{\Delta Q} = \alpha S_T \tag{4}$$

As indicated by Eq. (4), the relative sensitivity is proportional to both the TCR and S_T. It should be noted that the former is related to the sensing material properties and the latter to the sensor configuration design. This suggests that a better resolution can be achieved through an improvement of these two factors.

System Level Modeling

Modeling the electrical, thermal, and fluidic behavior of a microfluidic flow sensor and its surrounding structures will provide comprehensive information on many of the physical and dynamic behaviors of the thermoresistive flow sensors located within microfluidic environments [2]. An accurate device model and simulation offer the designer many advantages such as: reducing the time needed for the development cycle and providing the possibility for device optimization through software instead of iterations on physical devices. This, in turn, helps to reduce the end cost of the device. Here, we will focus on the thermal and fluidic modeling. The electrical effect of the sensor will be attributed to a lumped heat source term which appears in the thermal fluidic models.

Simulation on a flow sensor with its integrated control and signal processing electronics has to simultaneously take into consideration several different domains including the electrical (circuit electronics), heat transfer (thermal phenomena), and fluid flow [2].

As shown in Fig. 5 for the three-dimensional structure of a typical ►thermal anemometer, different types of heat transfer occur in and around the microchip structure [2]. Based on the model developed previously [2], a complete modeling of the thermal state of the flow sensors can be obtained as follows.

Clearly, conduction occurs in the SiO_2 layer, insulating the three flow sensor elements, the flow sensor elements themselves, and the bottom silicon substrate wall of the microchannel. The equations for characterizing the thermal state of these elements can thus be expressed as, respectively, [2]

$$\text{for SiO}_2\text{ layer:}\quad k_{SiO_2} \nabla \cdot (\nabla T) = (\rho c)_{SiO_2} \frac{\partial T}{\partial t} \tag{5}$$

$$\text{for heater:}\quad k_p \nabla \cdot (\nabla T) + \dot{q}_{heat} = (\rho c)_p \frac{\partial T}{\partial t} \tag{6}$$

$$\text{for sensors:}\quad k_{sens} \nabla \cdot (\nabla T) + \dot{q}_{sens} = (\rho c)_{sens} \frac{\partial T}{\partial t} \tag{7}$$

T

$$\text{for silicon substrate:} \quad k_{\mathrm{Si}} \nabla \cdot (\nabla T) = (\rho c)_{\mathrm{Si}} \frac{\partial T}{\partial t} \tag{8}$$

where k_{SiO_2}, k_p, k_{sens}, and k_{Si} are the thermal conductivities of the SiO_2 layer, polysilicon heater, sensor, and silicon substrate, respectively; $\dot{q}_{heat}$ and $\dot{q}_{sens}$ are the Joule heating rates at which energy is generated per unit volume of medium for the electrical heater and sensor, respectively; ρ and c are the density and specific heat for each of the solid materials, respectively.

Forced convection occurs in the microchannel where the liquid flowing through the microchannel carries heat away from the heater location. The liquid flowing through the microchannel is governed by the Navier–Stokes equations. By assuming that the flow includes viscous dissipation, the flow equations can be reduced to

$$k_{\mathrm{f}} \nabla \cdot (\nabla T) + \mu \left(\frac{\partial u}{\partial y}\right)^2 = \rho c_{\mathrm{p}} \left[\frac{\partial T}{\partial t} + u(y) \frac{\partial T}{\partial x}\right] ;$$
$$u(y) = 4u_{\max} \left[\frac{y}{d} - \left(\frac{y}{d}\right)^2\right] \tag{9}$$

where k_f, ρ, c_p, and μ are the thermal conductivity, density, specific heat, and viscosity of the fluid, respectively; u is the velocity of the fluid and u_{max} is the velocity of flow at the center line of the microchannel; d is the gap distance of a microchannel with a rectangular cross-section.

At the top surface of the SiO_2 layer in the device, natural convection and radiation occur due to heat being conducted to the surface of the device from the sensor heater. The boundary equation there can thus be formulated by equating the conduction of heat through and the effective convection on the top surface, i. e.

$$-k_{\mathrm{SiO_2}} \frac{\partial T}{\partial y} = h\,(T - T_\infty) \tag{9}$$

where h is heat transfer coefficient which has included the convection effect and radiation on the device surface, and T_∞ is the temperature in the free stream flow.

A constant temperature is assumed at the entrance of the microchannel bearing in mind that this site is exposed to the ambient temperature, i. e.

$$T\,(x = 0) = T\,(x = L) = T_\infty \tag{10}$$

where L is the length of the microchannel.

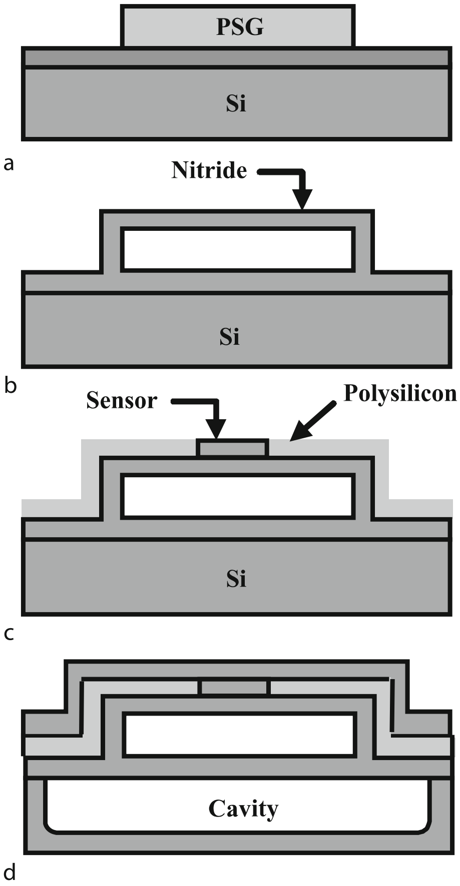
To obtain the above equations in a closed form, a series of continuum equations still need to be established. At the interfaces between the heater, sensor, and the surrounding solid material, there is a continuum equation which characterizes the heat conduction at the two sides. A convective heat transfer equation similar to Eq. (9) should be used for the interfaces between a solid surface and the surrounding flowing fluid.

A complete simulation of the above coupled equations and boundary conditions would help to give a complete picture of the detailed working process of the thermoresistive flow sensor including the electrical, thermal, and fluidic phenomena [2]. It would also provide a useful way to optimize the geometry and material of the whole fluidic device.

Device Fabrication

Realization of a flow sensor depends on its specific application. Overall, the spatial and transient resolution and the compatibility of the sensor within the desired device are of major concern [6]. In addition, the protection of the fluids and components demands a reduction in the thermal crossover from the flow sensor. The microflow sensors are usually automatically integrated with the microchannel during the fabrication process. The sensing element should be a resistor that has a resistance with high temperature sensitivity [2, 4, 9]. The heater of the sensor is often fabricated from a platinum or polysilicon resistor and acts as a microheater while the upstream and downstream temperature sensors are made from either polysilicon resistors or thermopiles. Such materials have excellent chemical resistance, biocompatibility, and high TCR [9].

The fabrication of a flow sensor includes making the microchannel and integrated sensor elements. Taking the fabrication of a single heater sensor in a suspended microchannel as an example, the general process involves the following basic sequences (Fig. 6) [7]: Fig. 6a: silicon wafer is often used as substrate. Its surface can be deposited with a thin silicon nitride layer as electrical insulation. A sacrificial PSG layer is then deposited and patterned on top of silicon nitride to define the microchannel geometry. Fig. 6b: Following the above procedure, another silicon nitride layer is deposited above the PSG surface to act as the top wall of the microchannel. After etching the PSG by HF, a microchannel can be formed. Fig. 6c: A polycrystalline silicon layer is deposited on the silicon nitride as the sensor, and then doped by B^+ ion implantation to improve its performance. This is followed by an annealing process. After that the polysilicon is patterned by plasma dry etching to define the sensor geometry. Fig. 6d: The sensors are sealed by uniformly depositing a thin silicon nitride layer. The inlet and outlet are then opened by KOH. Subsequently, contact opening and Al metallization will form connections between the macroworld and the sensing element. Finally, thermal iso-



Thermoresistive Flow Sensors, Figure 6 Main process steps for fabrication of MEMS flow sensors. Modified from [6]

lation of the channel is achieved by removing the silicon directly underneath the channel using gas-phase isotropic etching by BrF_3 or XeF_2. In this way, an integrated thermoresistive flow sensor with a microchannel is made. In a practical design, the structure, material and configuration, even the fabrication approaches (see Fig. 6) are subject to change depending on various specific demands.

Key Research Findings

Material matching is a critical issue when making a high quality sensor system. For example, Ni and Pt thin films have often been used as temperature sensing elements on GaAs substrate because of their high temperature coefficients and compatibility with GaAs-based devices and related IC processing steps [11]. But when deposited directly on GaAs, both films exhibit high chemical reactivity and interdiffusion effects on the GaAs interface mainly at elevated temperatures, which can lead to the degradation of their electrical and thermal properties. In order to suppress the interfacial interactions, a thin diffusion barrier layer has to be formed on the GaAs surface before the deposition of the Pt and Ni [11].

Several factors determine the measurement resolution of the microflow sensor [11]. First, the sensitivity of the sensor depends on the heater's TCR. Adoption of an appropriate doping concentration of the polysilicon thin film would improve the measurement resolution. For example, a slightly doped heater increases its resistance and hence reduces inaccuracies arising from the resistance of the leads and wires. Second, *thermoresistive flow sensors* require extremely good thermal isolation to avoid heat conduction in the wall. For the channel in direct contact with the substrate, the heat loss from the heater to the substrate may considerably reduce the sensor's sensitivity to the fluid flow. As a remedy, the microchannel can be suspended from the substrate to improve the thermal isolation. In this way, a flow rate measurement resolution in the nanoliter per minute range is possible [11]. On the other hand, it is also useful to insert a thermal insulation between the substrate and the fluidic channel. Further, to assure a fast response and low power consumption, free-standing microfilms with reduced dimensions and good thermal isolation are also very helpful. They are usually implemented using surface micromachining [8]. Such devices can be applied to both gas and liquid flow measurements and permit dynamical operation with complex heating and possible evaluation of the fluid flow parameters.

The maximum temperature measurement resolution depends on the spatial position of the sensor elements with reference to the distance between the heater and the sensor which can also be optimized. Computational modeling and simulation can provide a predictive capability and the means of evaluating the performance of a new design before hardware fabrication. The effect of varying the geometries of sensors and channel can be tested numerically, with different aspect ratios between them. Further, most fluid properties, which determine the heat transfer process, depend on the working temperature. It should be noted that, some changes to the fluid due to heating may not always be easily compensated. Therefore, accurate thermal flow sensors require both flow calibration and calibration for temperature compensation [4].

Future Directions for Research

Except for the normal microsize sensor devices, which have already been strenuously tested, much smaller *thermoresistive flow sensors* are in urgent need of investigation. However, this may involve a series of new challenges. With the decrease in the flow channel and sensor, conventional flow and heat transport theories may not be valid

to explain the phenomena, due to the multiple physical effects that are involved. Currently, there is still a strong lack of fundamental knowledge on such issues. In particular, the coupled momentum, electrical and heat transfer phenomena in the basic components of the flow sensor and the surrounding fluid and solid components are not well understood. It is possible that if the size becomes smaller, the flow and heat transfer, electrical field, and even mechanical properties such as the expansion effect in such devices may tend to behave differently compared to the behavior of their bulk objects. For example, the inertial force tends to be quite small and the surface effects, the electrical double layer, which were unimportant in the bulk device, will play a dominating role. Friction, electrostatic forces, and viscous effects due to the microfluid and channel may become increasingly important as the devices become smaller. Further, whether or not the specific fluid, usually a biosample, will follow the behavior of Newtonian fluids needs to be clarified experimentally. Additionally, with multispecies such as biological samples or chemical compounds in the micro- or nanofluidics, the thermoresistive flow sensor may encounter difficulty in realizing a high measurement solution and good repeatability. Multiparameter detection in micro- or nanoflows is thus a big challenge.

Overall, a large number of variables determine the measurement resolution of a thermoresistive flow sensor. Among the effects which influence the measurement, sensor material characteristics and liquid flow mode, the channel property, the flow quality, multicomponents, liquid properties and geometry of microchannels all need to be addressed. Previous investigations have provided quite substantial experimental data on the thermoresistive flow sensor. Future study can choose to follow some of the existing technical routes by carefully evaluating the size effects. Clearly, a complete modeling of the various domains in the flow sensor and incorporating the electrical, thermal and fluidic effects into the model are also worth investigating.

Thick film lithography

Definition

Thick film lithography refers to the processes used to make thick films of photoresist, i. e. typically "thick film" is used to refer to films that 5 to 100's of μm (μ) thick, and subsequently produce relief patterns in those films. The *photoresist* is a radiation sensitive material that is applied to a substrate surface, exposed to radiation to create a physiochemical change in the exposed regions, and washed in a developer solution to produce the desired physical relief patterns.

Overview

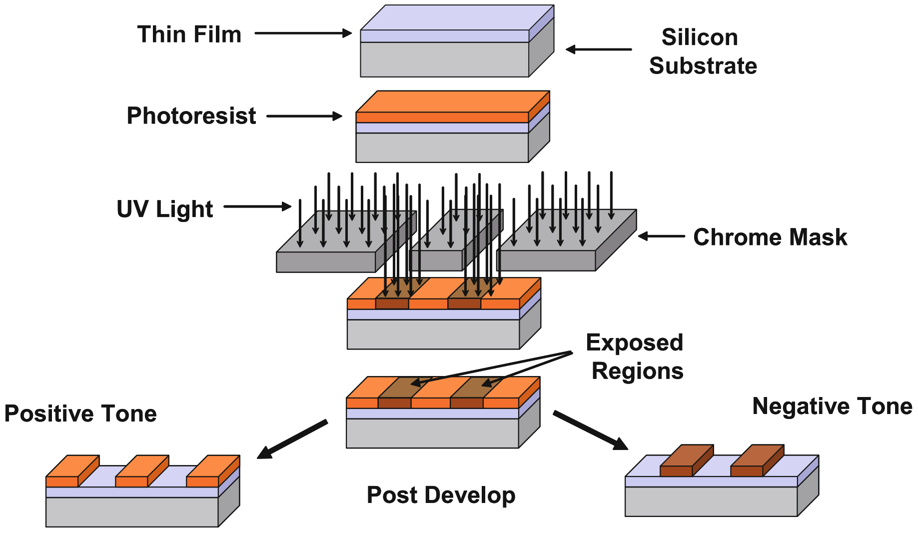
Lithography in the most general sense refers to methods used for printing on a smooth surface. It has its origins in methods used to print text and artwork onto paper or other suitable materials in the late 1700's. In the context of microfabrication and microsystems today (e. g. integrated circuits, microelectronic devices, microelectromechanical systems, and microfluidic devices), it refers to the processes used to form relief patterns in the photoresist films that are subsequently used in the layer-by-layer fabrication sequences of such micro-scale devices. It is also commonly referred to as microlithography or nanolithography depending on the size scale of features that are being printed. There are many specific types of lithographic processes. It is common to classify them by either:

- the type of external stimuli used to impart pattern definition in the resist (e.g exposure to ultraviolet light, exposure to an electron beam, exposure to x-rays, mechanical force using a mold or template, etc.)
- the type of photoresist being used (e. g. positive tone resist, negative tone resist, diazonapthoquinone-novolac resist, chemically amplified resist, single layer resist, bilayer resist, etc.), or
- the photoresist film thickness range being used (i. e. generally divided into thin film lithography and thick film lithography).

This discussion will be limited to those lithography methods that utilize the application of external radiation (i. e. optical exposure, e-beam exposure, or x-ray exposure) and will not include imprint lithography techniques such as hot embossing. Thick film lithography is generally used to refer to lithographic processes that utilize photoresist film thicknesses greater than 5μ in thickness.

The steps in a basic lithography process are shown schematically in Fig. 1. The first step in the process generally involves cleaning the surface of the substrate on which the lithography is to be performed, and may also involve the application of a surface priming agent. A wide variety of both wet chemical and dry plasma methods for cleaning the substrate surface may be employed. If surface priming of the substrate is performed, it can be done using both vapor phase and liquid phase exposure of the surface to an appropriate priming agent. Surface priming is generally done to improve the adhesion between the photoresist film and the substrate surface so as to prevent problems such as difficulty in wetting the substrate surface during spin coating of the photoresist or delamination of the photoresist film during further processing such as aqueous development. One of the most commonly used surface priming agents for spin coating resists is hexamethyldisilazane (HMDS) which reacts when applied to a surface containing hydroxyl groups (i. e. such as the silanol groups present on native oxide coated silicon wafers) to produce an essentially methyl terminated surface. The organic non-polar nature of this methyl terminated surface generally improves compatability between the surface and the photoresist, which is also typically an organic material of moderate polarity.

Once the substrate surface has been prepared, the photoresist film is applied. Application of the photoresist can be performed using several different methods, with dry film transfer, casting and in -situ polymerization, and spin coating being the most common methods. In dry film transfer, a pre-made solid photoresist film is laminated onto the substrate surface. This type of photoresist film deposition method is relatively common in thick film lithography since spin coating of thick uniform films can be difficult and thick photoresist films respond well to such film transfer methods. Spin coating is the other most common film deposition method and involves depositing the photoresist from solution, i. e. the photoresist solids are dissolved into an organic casting solvent, onto the substrate and subsequently spinning the substrate at moderate to high speeds. The spinning action spreads the solution into a uniform film and also serves to dry the film into a solid form. In cases where the film is spin coated onto the substrate, it is common to then heat the substrate and film in



Thick Resist Lithography, Figure 1 Schematic of the basic lithography process. First a resist film is coated onto the substrate of interest that may contain either films to be etched or films that can be used to deposit other materials by techniques such as plating. The resist film is exposed pattern-wise to radiation which results in a physiochemical change in the exposed resist that changes the solubility of the exposed resist in a developing solvent. Treatment of the resist with a developing solvent then leads to either removal of the exposed resist in the case of positive tone photoresists or removal of the unexposed resist in the case of negative tone photoresists

what is referred to as a post-apply bake (PAB). The purpose of this baking step is to further dry the film by evaporating remaining casting solvent in the photoresist film. After application of the film, the next step is to expose the film in a pattern-wise manner to produce a latent chemical image in the film in the shape of the desired final pattern. Depending on the specific type of resist and the type of radiation exposure source used, the type of physiochemical change in the resist film that ultimately leads to development of the desired relief image can vary quite widely. The most common types of thick film lithography are:

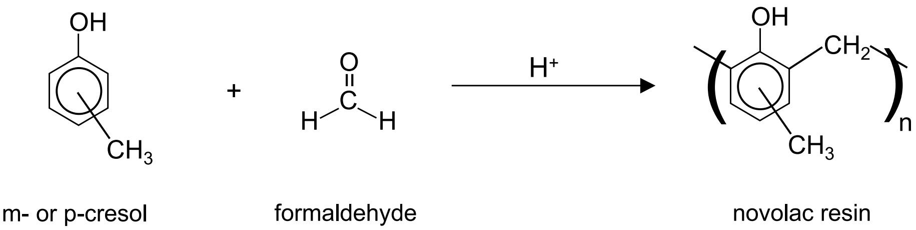
- positive tone imaging using ultraviolet exposure of *diazonaphthoquinone-novolac resists*,
- negative tone imaging using ultraviolet or x-ray exposure of cross-linking resists such as *SU-8*, and
- x-ray exposure of positive tone resists such as *poly(methyl methacrylate)* or PMMA. Further attention will be paid to each of these in the following section.

Basic Methodology

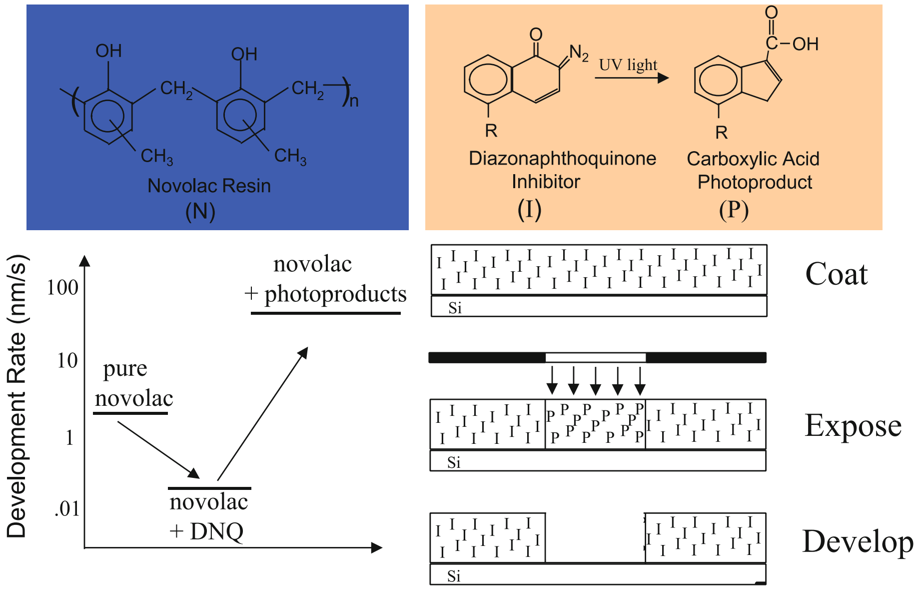
Positive Tone Thick Film Lithography using DNQ-Novolac Resists and UV Exposure

In a positive tone resist, the areas that are exposed to the radiation develop away into solvent faster than unexposed areas, resulting in a positive tone image of the mask. The majority of commercial, positive tone, non-chemically amplified resists used today are variations on the well-known, two component, diazonaphthoquinone-novolac resist. (5) Novolac is a name generally given to acid catalyzed phenol-formaldehyde condensation polymers of the type shown in Fig. 2.

Novolac polymers are soluble in a variety of common organic solvents. Resist films are typically cast from organic solutions (propylene glycol monomethyl ether acetate, or PGMEA, is a common solvent) to form isotropic, glassy, thin films. These polymers are also soluble in aqueous alkaline solutions due to the presence of the acidic phenolic functionalities on the polymer backbone. It is this base solubility that is exploited in the development process. In order to print a relief image in a photoresist it must be possible to modify the dissolution rate of the resist upon exposure to radiation. It is not the novolac polymer in DNQ-novolac resists that is sensitive to radiation. Instead, it is the second component of the resist, the diazonaphthoquinone (DNQ), that is responsible for the ability of the resist to change its dissolution behavior upon exposure to radiation. DNQ is often referred to as the photoactive compound (PAC) or sensitizer in the resist, since it is the component which responds to radiation exposure. Thus, the role of the novolac polymer in these resists is to provide the desired physical characteristics of the material, such as good film forming properties and etch resistance to plasma processing, while the DNQ allows the resist to be imaged. Figure. 3 shows a schematic view of the basic mechanism responsible for the function of DNQ-novolac photoresists.



Thick Resist Lithography, Figure 2 Example of the structure of a novolac resin and the commercial production route for the polymer that is typically accomplished via the acid catalyzed polymerization of cresols with formaldehyde



Thick Resist Lithography, Figure 3 Schematic picture of the mechanism by which DNQ-novolac resists function. Addition of DNQ inhibitor (I) to novolac polymer (N) results in a dramatic reduction in the dissolution rate of the polymer in aqueous alkaline developer solutions. Exposure of the DNQ-novolac resist mixture causes a chemical reaction converts the diazonaphthoquinone to a carboxylic acid photoproduct (P), and the presence of this carboxylic acid product in the exposed resist either does not dramatically retard or may in fact accelerate the dissolution of the polymer in aqueous alkaline developers. This differentiation in dissolution rate of the resist upon exposure allows for the formation of relief images in the photoresist after development

The addition of diazonapthoquinones to novolac films leads to a reduction in the dissolution rate of the polymer film in aqueous base relative to the dissolution rate of the pure polymer. This difference in rate can be as large as several orders of magnitude. Diazonaphthoquinone is therefore termed a "dissolution inhibitor" due to its ability to retard the dissolution rate of the novolac film. As shown above, DNQ undergoes a series of reactions upon exposure to radiation to form a carboxylic acid product. This carboxylic acid, unlike the hydrophobic DNQ, is soluble in aqueous base and its presence in the polymer film does not retard the dissolution rate in aqueous base. In fact, the presence of the carboxylic acid often serves to increase the dissolution rate of the novolac several orders of magnitude relative to the pure novolac polymer. It is this change in the dissolution rate of the novolac film due to the reaction of the diazonaphthoquinone with light that allows for the formation of relief images in the resist film. One advantage of DNQ-novolac resists for use in thick film UV lithography is that the resist material becomes more transparent to ultraviolet light, referred to as "bleaching" of the resist, as it is exposed. This bleaching phenomena allows thick resist films to be exposed and developed to produce high aspect ratio patterns relatively easily.

In forming thick resist films using DNQ-novolac resist solutions, solutions containing a high solids content of relatively high molecular weight resist polymers are typically used to provide high solution viscosities that make such thick film formation possible. In general, the relationship between film thickness formed after spin coating (t), spin speed (Ω), polymer concentration (C, typically in grams polymer/ 100 mL of solution), and resist polymer molec-

ular weight ($[\eta]$, as measured by intrinsic viscosity in this case) can be expressed as follows:

$$t = K\frac{C^{\beta}[\eta]^{\gamma}}{\omega^{\alpha}} \quad (1)$$

where K is an overall proportionality constant and *a, b,* and *g* are constants, all of which depend on the particular resist, substrate, and resist processing system used. Once a few experimental data points are collected, for example on the effect of spin speed on resist thickness, Eq. (1) can in general be used to develop a master equation for a resist coating application that can allow for specific resist thickness targets to be achieved. Before applying the resist, the substrate is generally cleaned and may be surface primed as mentioned earlier. In addition, in the case of UV exposure a so-called *anti-reflection coating* (ARC) may also be applied to the substrate. The purpose of such an ARC is to minimize surface reflections during UV exposure of the resist that can lead to undesired exposure variations in the resist, such as the formation of standing waves, that lead to degraded lithographic performance (e. g. the formation of scalloped sidewalls in developed relief images).

Exposure of DNQ-novolac resists is typically done using either I-line 365 nm, G-line 436 nm, or broadband ($\sim$ 350–450 nm) ultraviolet exposure using mercury lamp-based exposure tools. A variety of different types of exposure tools including contact, proximity, and projection exposure tools are used to perform the pattern-wise exposure of such materials. The maximum feature resolution of such exposure tools depends on the tool type, with projection exposure tools exhibiting the highest resolution and proximity tools exhibiting the lowest resolutions. Typical ultraviolet exposure doses for DNQ-novolac resists are on the order of several hundred mJ/cm^2 to several thousand mJ/cm^2 depending on the resist thickness, wavelength used, and formulation. After exposure, DNQ-novolac resists may be subjected to a post-exposure bake (PEB) that is designed to eliminate any significant gradients in DNQ concentration normal to the substrate surface. Such gradients are common in thinner film exposures using near monochromatic exposure sources since standing waves can form in the film during exposure that lead to a sinusoidal-looking concentration profile though the thickness of the resist film. Such oscillating concentration profiles make development of high quality features difficult and lead to scalloped edges in final resist relied profiles. Finally, the resist film is either immersed or sprayed with an aqueous alkaline developer to remove the exposed regions of the resist. Both inorganic alkaline developers (e. g. based on potassium hydroxide or KOH) and organic alkaline developers (e. g. tetramethyl ammonium hydroxide or TMAH) can be used for DNQ-novolac resists.

Positive Tone Thick Film Lithography Using X-ray Exposure

X-ray exposure of samples to fabricate thick film resist structures has developed into an important technique for microfabrication of a wide variety of devices. The use of x-rays to expose thick film resist samples is advantageous for a variety of reasons including:

- a simple printing scheme such as shadow masking (i. e. proximity or contact printing) can be used while still producing high aspect ratio structures with relatively straight sidewalls and
- x-rays have the ability to penetrate and expose the resist film with good uniformity throughout the depth of very thick film samples leading to more uniform structures.

The use of such x-ray exposure techniques is the basis for the so-called *X-ray* LIGA process. LIGA is the German acronym for lithography (LI thographie), Electroplating (G alvanoformung), and Molding (Abformung), which is a microfabrication process that was developed in the late 1970's and early 1980's by a team at the Forschungszentrum Karlsruhe. It was developed to allow the manufacturing of very high aspect ratio parts, in this case nozzles for uranium separation, with lateral precision below one micron. The basic original process involves five key steps steps:

- use of x-ray exposure to produce a high aspect ratio resist structure that can serve as a mold for electroplating,
- electroplating into the resist mold to form a metal master part attached to the substrate,
- removal of the resist layer,
- manufacture of a mold from the metal master part, and
- reproduction of copies of the metal master part by injection molding or other techniques.

Since its invention, this type of LIGA process, and many other variations on it, have been used for fabricating a wide variety of *microelectromechanical systems* (MEMS) and other microdevices.

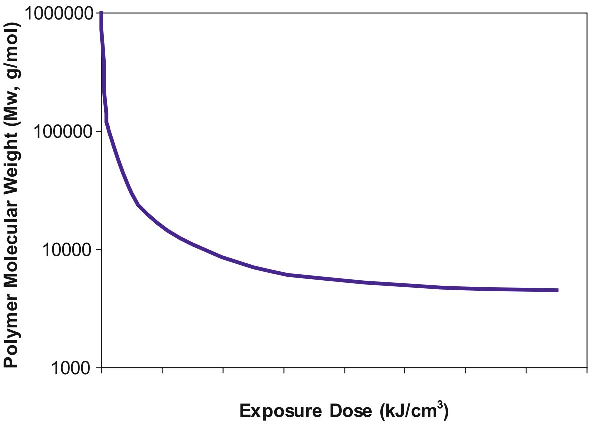
The original resist used for the LIGA process was thick films of poly(methyl methacrylate) (i. e. PMMA). Because spin coating the very thick layers desired in the original work was not a practical way to obtain thick homogeneous resist films, other alternatives were developed for producing the desired resist layers that were hundreds of microns to millimeters thick. The maximum film thickness reported when spin coating PMMA has been on the order of 150 μ. One technique developed for producing the thick PMMA films desired is the so-called "film casting" process in which:

- PMMA polymer is dissolved in methyl methacrylate monomer to form a very viscous mixture,

- a polymerization initiator and potentially cross-linkers and adhesion modifying compounds are added to the mix,
- the liquid is poured onto the substrate, put into a press configuration where a plate is placed on top of the liquid film and pressed down onto spacer shims located between the substrate and plate (i. e. to control the final film thickness),and
- the material is cured by heating the material or exposing it to ultraviolet light.

One problem with this casting method is the shrinkage that occurs as a result of the polymerization which makes film thickness control somewhat challenging and creates residual stress build-up in the polymer film. This residual stress build-up can be very problematic and can lead to crazing and delamination of the film from the substrate. In order to minimize such problems, very high molecular weight polymers are desired with preference to somewhat networked materials formed through the use of cross-linking agents (e. g. multi-functional acrylate monomers). Furthermore, post-cure annealing steps in which the film and substrate are heated above the glass transition of the polymer can help to reduce residual stress. Another set of techniques that have been used to generate very thick PMMA films involves the lamination of a pre-formed PMMA sheet onto the substrate. In one version of such a process, commonly referred to as a "glueing process", a thin layer ($\sim < 10$ thick) of the polymer-monomer mixture used for the film casting process is spread onto the substrate and the pre-formed PMMA sheet is pressed onto this layer which acts as a glue to stick and bond the sheet to the substrate. The glue layer is then cured to produce a secure bond of the sheet to the substrate. Studies of this technique have shown that the residual stress built up in the glue layer is much lower than that of the film casting technique since the amount of material cured is much smaller. In one final variation of this sheet bonding process, a thin ($\sim 1-2\,\mu$ thick) PMMA layer is first deposited onto the substrate via a method such as spin casting. After the film is cast, a small amount of a good solvent for PMMA is sprayed onto the film and the pre-formed PMMA sheet is pressed onto this solvent rich layer. The presence of solvent results in a melting and fusion of the sheet to the cast film and the process is complete in a few hours as the solvent dries from the thick film.

Upon exposure to x-rays, PMMA undergoes a variety of complex reactions. However, the dominant effect is chain-scission of the polymer which reduces its molecular weight. Figure. 4 shows the effect of x-ray dose on molecular weight for PMMA possessing a relatively high initial molecular weight (i. e. 10^6 g/mol) It is this reduction of molecular weight of the polymer in the exposed areas



Thick Resist Lithography, Figure 4 Example of the effect of x-ray irradiation on the molecular weight of an initially high molecular weight poly(methyl methacrylate) sample

that is responsible for the increased dissolution rate of the exposed PMMA in developing solvent. As can be seen, there is a point of diminishing returns in terms of using higher exposure energies. This is because as the polymer molecular weight decreases, the chance for cross-linking reactions in the PMMA increases, leading to the fact that at very high doses an equilibrium between chain scission and cross-linking reactions occurs that results in no further change in polymer molecular weight. After exposure, the irradiated regions of the polymer must be selectively remove using a solvent without attacking the unexposed regions. Special multi-component solvent mixtures are commonly used for the development. One example of a solvent developer that has been widely used is a mixture consisting of 20 vol% tetrahydro-1,4-oxazine, 5 vol% 2-aminoethanol, 60 vol% 2-(2-butoxyethoxy)ethanol, and 15 vol% deionized water. The molecular weight cut-off that the developer can dissolve can be adjusted by slight compositional changes to the developer or by simply adjusting the developer temperature. Increasing the developer temperature enables the dissolution of high molecular weight polymer, but temperatures above ~45 °C should be avoided as even very high molecular weight polymer is swollen or dissolved above these temperatures.

Although PMMA is well known for its ability to produce extremely high resolution patterns, it is also known for its relatively low radiation sensitivity. This results in the use of very high radiation doses to pattern the material. Furthermore, in thick resist layers, the absorption of energy by the material can not be ignored and leads to a variation in the energy deposited as a function of depth into the resist film. There is a minimum energy that must be deposited in the bottom of the resist film, otherwise the polymer at

T

the bottom of the film will not undergo sufficient chain scission to develop cleanly and will leave a residue. Likewise, there is a maximum amount of energy that can be deposited into the top of the resist film without resulting in foaming of the resist due to the release of gaseous byproducts during the chain scission process. As a result of these issues, the exposure conditions for PMMA in x-ray thick film lithography must be carefully considered and must take into account the limits for energy deposited into the top and bottom of the resist film.

Negative Tone Thick Film Lithography Using UV and X-ray Exposure of Cross-linking Resists

In the two previous examples, different physiochemical mechanisms were employed to increase the solubility of the exposed resist in developer that led to positive tone image formation. Negative tone imaging can also be performed by invoking physiochemical changes in the resist upon radiation exposure that leads to a decrease in the solubility of the exposed resist in developing solvent. The most popular method for producing such negative tone materials is the use of radiation induced cross-linking reactions in a polymer matrix. Cross-linking of the polymer in general to a reduction of the solubility of the polymer in developing solvent, in a manner that is exactly opposite to that used in x-ray lithography of PMMA. One of the most popular resists for negative tone thick film lithography is SU-8. SU-8 consists basically of a phenolic oligomer that has been functionalized with epoxide groups mixed with a photoacid generator (e. g. an onium salt such as triphenyl sulfonium hexafluoroantimonate). Upon exposure to radiation, the photoacid generator compound produces a strong acid and this acid in turn initiates polymerization of the epoxide groups on the oligomers. This results in heavy cross-linking of the film and a dramatic reduction in its solubility. In addition to providing a mechanism for patterning the resist, the use of the cross-linking reaction produces a very mechanically robust polymer that is often used to directly form structures that are used as a part of the final device being constructed and not simply as a temporary resist mask for other processes such as plating.

Key Research Findings

X-ray based thick film lithography is still the best technique for producing very high aspect ratio structures with little or no variation in part dimensions along the axis normal to the substrate. This ability to produce such high aspect ratio structures with excellent dimensional tolerancing is a result of the very small x-ray wavelength combined with the ability to produce very well collimated x-ray beams using synchrotron sources. Parts that are hundreds of microns to millimeters in thickness with lateral feature resolution well below one micron can easily be formed. However, access to a synchrotron source is required for such x-ray techniques which makes the method impractical for most laboratories or companies. As an alternative, thick film lithography using UV exposure has progressed to the point where it is the dominant over x-ray techniques for MEMS and other thick film fabrication needs. Both positive and negative tone resists are used in such methods, with negative tone materials offering the advantage that they generally have superior mechanical properties that can allow for their permanent use in device structures.

Future Directions for Research

Thick film lithography at this point is a relatively mature technology. While techniques such as x-ray lithography can produce very high aspect ratio structures in very thick resist films, the use of such x-ray techniques is limited by extreme expense of the synchrotron sources needed to produce the well collimated x-ray beams required for such lithography processes. Therefore, work continues to develop much cheaper alternatives based on the use of ultraviolet exposure using both positive and negative tone resists that can produce high aspect ratio structures with high feature resolutions. Such UV exposure methods are now used in so-called UV LIGA in a manner that is analogous to the x-ray LIGA methods discussed earlier. In addition, modern MEMS devices rely on the ability to fabricate released structures, i. e. ones where some part of the device is not in contact with the substrate or some other part of the device. Various sacrificial techniques have been developed in conjunction with thick film lithography to produce these released structures. Development of materials and techniques for the direct use of the resist material as a sacrificial material continues to be of interest. In one example, sacrificial resists based on polynorbornenes and polycarbonates have been developed that can be used for thick film lithography, used to template the deposition of additional materials via plating or other techniques, and finally removed as a sacrificial material by simply heating the resist to a moderate temperature that is capable of transforming the polymer into gaseous products. Using such materials and techniques, microchannels and microfluidic devices have been fabricated with very complex designs in a manner that is compatible with both other microelectronic and MEMS fabrication techniques.

Synonyms

3D electrodes; Flow-through electrodes; Porous electrodes

Definition

Three-dimensional electrodes are non-planar electrodes that typically improve the transport of redox species to the electrode surface increasing current density. Some 3-D electrodes are solid, but others are porous or flow-through electrodes whose effective surface area is greater then the geometric surface area on the device.

Overview

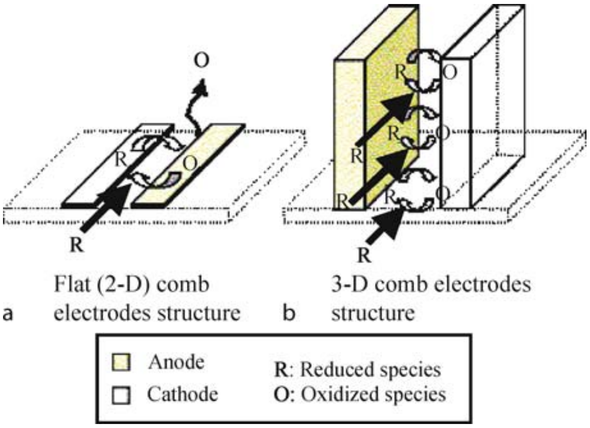
One of the common challenges of high sensitivity electrochemical analysis and high power density electrochemical power sources is the need for fabrication of three-dimensional electrodes. Historically, three-dimensional electrodes have been the focus of battery technology for decades and flow-based macroscale three-dimensional electrodes have been used for electrosynthesis [1], electrowining [2], photocatalytic reactors [3], and different types of chemical analysis [4, 5]. The electrodes were fabricated from a number of high surface area and high porosity materials like reticulated vitreous carbon (RVC). Over the last few years, scientists have developed microscale three-dimensional electrodes and have started employing them in microfluidic and nanofluidic devices. These microscale three-dimensional electrodes show promise for improving sensitivity of Lab-on-a-Chip devices and improving control in cell sorting and manipulation.

Basic Methodology

The main principle of employing microscale three-dimensional electrodes is to increase the effective surface area of the electrode to increase current, because amperometric and voltammetric current (i) or electrochemical flux is directly proportional to true electrode area (A).

$$i \propto A$$

Electrochemical current, typically referred to as faradaic current, is a measurement of reaction rate, so the more surface area for reaction, the more product that will be formed and the higher the current. This is illustrated in Fig. 1, which shows the effect of the increase in surface area (via a 3-D electrode) on the number of reactions (turnovers) that can occur at a given point in time. Frequently, the factor by which the current is increased is referred to as the roughness factor, which is the



Three-Dimensional Electrodes, Figure 1 Comparison between flat and 3-D electrodes [13], Reproduced with permission from each of the publishers

ratio of the true electrode area to the geometric electrode area, but the concept of the roughness factor gets more complicated with flow-through electrode geometries. However, over the last few years, other purposes for 3-D electrodes have emerged. 3-D electrodes are also useful in the field of dielectrophoresis and electrohydrodynamics.

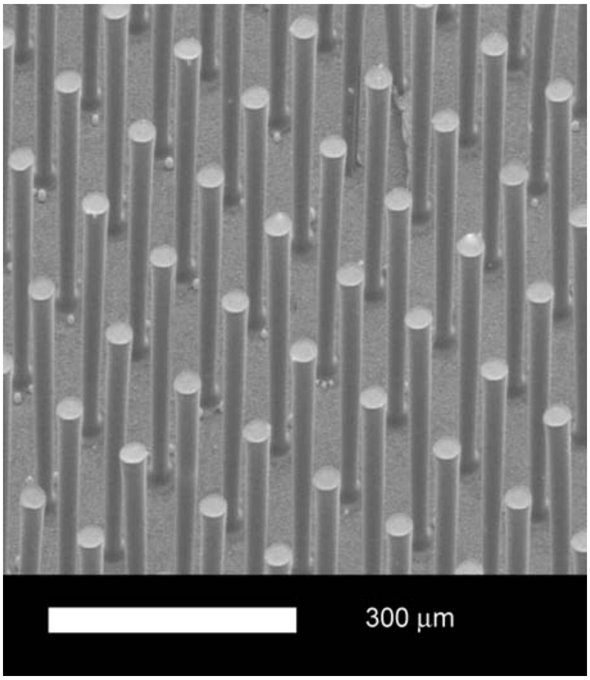
Dielectrophoresis is sometimes confused with electrophoresis and electroosmosis, but electrophoresis and electroosmosis involve the movement of charged species in a high electric field, but dielectrophoresis is the flow phenomenon by which neutral species can be transported by inducing a spatially non-uniform electric field. There are two types of dielectrophoresis: positive dielectrophoresis and negative dielectrophoresis. In positive dielectrophoresis, sub-micron species move toward high electric field regions, wherein negative dielectrophoresis results in sub-micron species moving toward low electric field regions. Dielectrophoresis is particularly helpful in separating sub-micron species (which cannot easily be separated with traditional filters) and allowing for the deliver of sub-micron species to specific areas of the microchip. It is important to note that all particles can experience dielectrophoretic forces, but the strength of the force predicts the observed dielectrophoretic effect. The strength of the force is dependent on the size and shape of the particle, the electric field gradient, dielectric constant of the solution, and dielectric constant of the particle in the solution. 3-D electrodes allow for a better method for extending the electric field within the solution for improved 3-D control through the solution reservoir and can be designed to have better local control over the dielectrophoretic movement [6].

The final use of 3-D microelectrodes is electrohydrodynamics. Electrohydrodynamic fluid flow is similar to magnetohydrodynamics, but instead is developed by applying a high frequency electric traveling wave, which induces net fluid flow by exerting a force on the charges in the bulk liquid. It is advantageous compared to magnetohydrodyanics or even mechanical pumping, because it is pulseless (continuous) and capable of controllable deliver of very small amounts of fluid, as well as requiring low voltages (around 10V) [7]. Miniaturization of the electrohydrodynamic pump has the advantages of providing the opportunity for bi-directional flow and the ability to more quickly turn the flow on and off.

Key Research Findings

Carbon MEMS (C-MEMS)

Interdigitated arrays of carbon electrodes can be fabricated from pyrolyzing photoresist, as shown in Fig. 2. These electrodes are formed by fabricating a prepatterned photoresist structure using photolithography. The photolithographic process involves coating a surface (typically a silicon wafer) with an organic photoresist (i. e. SU-8) and then exposing the photoresist to UV light through a mask that will define the size, shape, and placement of the carbon electrodes. Then, the photoresist is developed, so that the only remaining structures on the substrate are the UV-crosslinked photoresist structures. The substrate is then pyrolyzed at high temperature ($> 900\,°C$) to form the 3-D carbon electrodes. These electrodes have similar properties to glassy carbon, but with lower oxygen content. They are particularly useful for 3-D electrodes, because they can be fabricated with high aspect ratios (up to 20:1), to tall structures can be fabricated easily and reproducibly. These pyrolyzed photoresist 3-D electrodes have applications in batteries, but they are also applicative to microchip bioanalysis systems. Fischer et al. have used pyrolyzed photoresist to make 3-D electrodes for dual amperometric detection for microchip electrophoresis [8]. However, it is important to note that many electrodes for microchip electrophoresis are 3-D electrodes and can be fabricated from a number of sources including carbon-based screen printing inks, precious metal-based screenprinting inks, carbon fibers, electroplating of metallic electrodes, vapor deposition of metallic electrodes, etc. The choice of material is



Three-Dimensional Electrodes, Figure 2 Array of carbon microelectrodes produced by pyrolizing photoresist [14], Reproduced with permission from each of the publishers

usually a function of the properties of the analyte being measured and the type of microchip being fabricated. In theory, these same increased surface area electrodes can be used for micro- flow injection analysis and other amperometric biochips. For instance, micromolded screen printing inks can be used to study the release of catecholamines from PC12 cells [9]. Beyond employing 3-D electrodes for electrochemical detection, Park et al. have used the pyrolyzed photoresist 3-D electrodes for dielectrophoretic separation of carbon nanofibers from canola oil, cell sorting (separation of living and dead cells, cancer cells and leukocytes from blood, and even one type of bacteria from another), and engine oil filtering for sub 10 micron particles [6].

Other Fabrication Methods

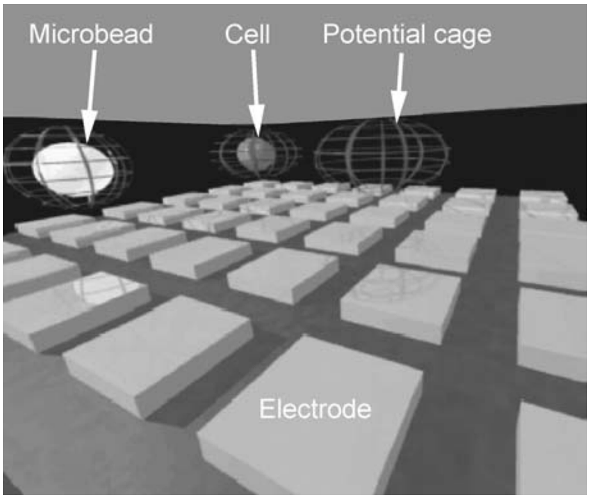
Although there are a wide variety of methods for fabricating 3-D electrodes, they can be simply characterized as top-down approaches or bottom-up approaches. The top-down approaches typically involve ablating or etching a large structure down to a 3-D micro or nanostructure. This is frequently done to form micro- and nanoscale electrode tips, but is not as frequent in microfluidic and nanofluidic devices as compared to electrodes for scanning electrochemical microscopy (SECM) and other static solution electrochemical devices. Most 3-D electrodes in microfluidic and nanofluidic devices are fabricated from a bottom-up approach (like the C-MEMS discussed above). This can be done for metallic electrodes by sputter coating or vapor depositing metal structures on substrate surfaces (frequently with the help of an adhesion layer, depending on the substrate surface) or by electrodeposition/electroplating through a template. However, there are other fabrication methods including screen printing 3-D electrodes and micromolding with screen printing inks. The process of screenprinting conductive inks is a well developed technology and can be used for fast mass-production of electrodes, but micromolding is a relatively new technology develop by Martin et al. [10] by which a PDMS microfluidic mold is used and the mold is placed over the substrate. Screen printing ink is pulled through the mold and then the mold/ink/substrate are cured and the mold is removed. The result is 3-D carbon electrode with similar properties to a screenprinted 3-D electrode that can be used for amperometric or voltammetric detection and can easily be coupled to microchip electrophoresis. These types of electrodes can also be used in microfluidic biofuel cells, because the micromolding technique can be used to deposit both the electrode and the enzyme immobilization membrane for entrapping the enzyme at the surface of the electrode.

Microfluidic Chambers for Studying Cellular Responses to Electrical Stimulation

In electrochemistry, we normally define 4 types of electrode designs: a single electrode, a dual electrode, an electrode array, and an individually addressable electrode array. The single electrode is used for simple amperometric and voltammetric detection or as the anode or cathode in a battery or fuel cell. The single electrode can be used in either a 2-electrode or 3-electrode electrochemical cell. The 2-electrode electrochemical cell is the typical battery design with a single electrode and a counter electrode, which we can consider a cathode and an anode. The 3-electrode electochemical cell contains the single electrode (frequently referred to as the working electrode or sensing electrode), a counter electrode for completing the circuit, and a reference electrode in a feedback circuit to ensure the proper applied potential. The dual electrode system is used for dual detection systems in either a 3-electrode or 4-electrode electrochemical cell. The 3-electrode cell contains the two working electrodes and a single counter electrode, whereas the 4-electrode cell contains the dual working electrodes, a counter electrode, and a reference electrode.

Electrode arrays are different from single electrodes, because frequently the electrodes are so close together that the electric field and concentration gradient at one electrode can affect the other electrode. There are two types of electrode arrays: a simple electrode array and an individually addressable electrode array. The simple electrode array contains a series of small micro- or nano-scale electrodes that are all connected together (similar to a group of electrodes wired in series), so that the potential (voltage) that is applied is the same for all electrodes. This type of electrode is used to increase the current density of system, but is not helpful for dielectrophoresis or 3-D detection or stimulation, whereas a individually addressable electrode array has a group of electrodes, but a different potential (voltage) can be applied to each electrode and the current can be measured for just that electrode. The individually addressable electrode array is a relatively new technology, but is crucially important in detection schemes for complex systems and the ability to control transport on the microscale.

Three-dimensional microelectrode arrays can also be used for stimulation of cell versus separation or detection. Klauke et al. developed a microchip device for studying cellular responses to electrical stimulation of myocytes. A polydimethylsiloxane (PDMS)-based microchip was fabricated that include an array of three-dimensional gold microelectrodes for stimulation of mycotes cultured on the surface of the chamber. Measurement of action potential,



Three-Dimensional Electrodes, Figure 3 Schematic of biochip for dielectrophoresis-based cell separation and trapping [15], Reproduced with permission from each of the publishers

intracellular calcium concentration and cell shortening can be performed in-situ within this device [11].

3-D Electrodes for Cell Manipulation

Three-dimensional electrodes on microchip devices have also been used for cell manipulation via dielectrophoresis. Dielectrophoresis can be used to move neutral particles (like cells) by inducing a spatially non-uniform electric field, which will either force the particle to low or high potentials. Microchips have been fabricated with 102,400 addressable electrodes of 20 micron x 20 micron [12]. A schematic of the microchip is shown in Fig. 3. Varying potentials were applied to the electrode to move cells and trap them into regions for optical detection [12]. This is off particular interest for single cell detection and also for the separation of different types of cell (cancer vs. normal, etc.). However, this type of device requires a complicated individually addressable electrode array instead of just an electrode array, because the non-uniform electrode fields must be controlled precisely to move the cell to the proper place on the chip and then to trap the cell. This particular technology and the control circuitry allowed for the software controlled movement of 10,000 living cells simultaneously [12], which is a significant advancement in both the capacity of the chip, but also the logic, circuitry, and software to be able to handle the increased capacity.

Future Directions for Research

These type of 3-D electrodes on microchips could also be used for a wider variety of biomethods, including electroporation, drug delivery, and electrostimulated cell culturing. 3-D electrodes will also have applicability in laminar flow-based fuel cells and biofuel cells due to the increase in roughness factor. 3-D electrode for dielectrophoresis also have applicability to nanoliter or sub-nanoliter liquid dispensing.

Threshold Filter

Definition

With a threshold filter binary images can be created. A threshold of a defined intensity value is set and all pixel intensity values above this threshold are 1 while the others are 0. If only pixel values are set to 0 whose original intensity value is smaller than the threshold, a ► background subtraction can be done. This is often done to divide objects from background.

Time-Gated Fluorescence Detection

Synonyms

Fluorescence detection

Definition

Time-gated fluorescence detection is used to monitor the fluorescence of a sample as a function of time after excitation by a flash or pulse of light. Steady-state intensity measurements of emitted fluorescence are taken over a period of time following pulsed excitation. Time resolution is optically gated, whereby a short laser pulse acts as a gate for the detection of emitted fluorescence and only fluorescence that arrives at the detector at the same time as the gate pulse is collected. In time-gated detection systems, the detector is turned on after excitation and the fluorescence intensity generated is integrated. This method is useful for long lifetime probes.

Time-Multiplexed Deep Etching

Synonyms

Time-multiplexed plasma etching

Definition

Time-multiplexed deep etching (TMDE) is a special deep reactive ion etching (DRIE) process, and has been commonly applied in inductively coupled plasma (ICP) etching system for anisotropic etching and 3-D microstructure fabrication.

In TMDE, the process conducts the cycling of etching and passivation steps. In each cycle, plasma processing gases are flowed independently one at a time during operation which is known as the Bosch process patented by Robert Bosch GmbH of Germany in the mid-1990s. The etching step forms a shallow isotropic trench in a substrate (typically silicon). The passivation step forms a protective film on all surfaces of the substrate. In the subsequent etching step, ion bombardment promotes the preferential removal of the passivation film on the horizontal surface and further attack the substrate chemically and physically, allowing the profile to evolve in a highly anisotropic structure. In a typical configuration,SF_6 is the etching gas andC_4F_8 is the deposition gas for sidewall passivation. In TMDE processing, gas flow rates, etching durations and working powers in each step can be varied to produce designed 3-D microtructures with the well-controlled sidewall profiles.

TIRF

Synonyms

Total Internal Reflection Fluorescence (Microscopy); TIRM; TIRFM

Definition

Total internal reflection fluorescence microscopy (TIRFM), or simply TIRF, is the application of fluorescence imaging to evanescent wave microscopy. The material of interest is tagged with fluorescent material that emits light at wavelengths greater than the excitation photons from the evanescent field, which additionally improves the detectability of the evanescent wave microscopy technique.

T

Definition

Techniques for transferring samples to microfluidic chips are of crucial importance because they open the microchip to the macroworld. ►Sample introduction is the beginning of the process of microfluidic analysis on chips. Various techniques for transferring samples in the form of liquid, gas or aerosol to an on-chip liquid environment have been reported for biochemical and environmental analysis.

Overview

Microsystems based on microfluidic chips, are of considerable recent interest owing to their high degree of integration, portability, minimal solvent/reagent consumption, high performance and speed. The dramatic downscaling and integration of chemical assays hold considerable promise for faster and simpler on-site monitoring and decentralized clinical testing and make these analytical microsystems particularly attractive for biological, environmental, and industrial analysis. As with other analysis systems, techniques for transferring samples to microfluidic chips are one of the most important steps for microfluidic analysis on chips. Sample introduction is an important component of these systems and is an essential process for making chip electrophoresis a widely applicable analytical technique. A major obstacle to the realization of such real-life applications has been the introduction of the sample into such microchip devices.

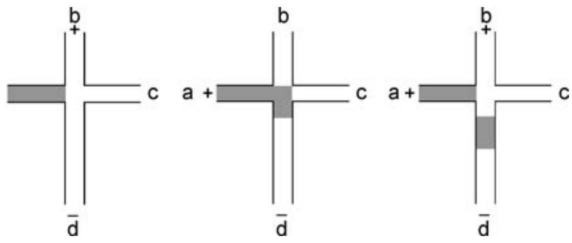
Samples are usually introduced into a microfluidic chip via ►solution reservoirs on chips that are simply storage units for the reagents and samples used within the manifold. Several types of reservoirs have been reported as fabrication techniques have progressed. Effenhauser et al. [1] have developed a simple method that has been commonly used. A blank glass plate (typically 1 mm in depth) was thermally bonded onto the etched chip containing the microstructure, in order to seal the system. Holes were then drilled into this top plate to provide access points to the microchannels. Plastic pipette tips were inserted into these holes to act as reservoirs and to hold the electrodes.

Transferring samples to chips requires the introduction of a reproducible sample into a flowing carrier stream of a manifold without any disturbance to the carrier stream. The system is more versatile if the reproducible volume range that can be introduced is wider. An ideal sample-induction system performs this as a convenient and fast operation so as to provide a high sampling rate. Conventional flow-injection analysis (FIA) injectors (e. g., rotary/slide valve injectors) cannot be used successfully in a microfluidic environment because of the demands of injecting very small volumes. However, some methods for transferring samples based on electrokinetic mobility (electrophoretic mobility or electroosmotic flow), miniaturized valves and hydrodynamic pressure methods employed in micro-FIA system have been adapted to be compatible with the microchip system. Many of the sample-transfer techniques used in the microfluidic chip system were initially adapted from techniques employed in conventional FIA and capillary electrophoresis (CE). Various techniques for transferring samples in the form of liquid, gas or aerosol to an on-chip liquid environment have been reported for biochemical and environmental analysis within the last decade.

Basic Methodology

Samples were usually transferred to the microfluidic system by electrokinetic injection and ►pressure injection. ►Electrokinetic sample introduction is most commonly used for transferring samples to chips. This can be attributed to factors such as the simplicity in achieving electroosmotic flow (EOF), i. e., no moving parts and minimal backpressure effects. The EOF in the microchannel acts as a pump and can easily be controlled by outside high voltages. The two commonly employed injection modes for microfluidic chips are time-based and discrete volume-based injection. In the case of the time-based (or gated injection), the amount of sample introduced into the carrier stream can be controlled by adjusting the injection time.

Figure 1 illustrates the time-based floating injection. The running buffer (Fig. 1b) and unused (Fig. 1c) reservoirs were filled with running buffer solution, while the sample reservoir (Fig. 1a) was filled with a sample mixture. The detection reservoir (Fig. 1d) was filled with the running buffer solution. A high voltage was applied to the sample reservoir to facilitate the filling of the injection channel, while the detection reservoir was grounded and all the other reservoirs remained floating. The sample solution was loaded into the separation channel by applying an injection voltage to the sample reservoir for several seconds, while the detection reservoir was grounded and other



Transferring Samples to Chips, Techniques, Figure 1 Operation processes of time-based floating injection. (**a**) sample reservoir, (**b**) running buffer reservoir, (**c**) unused reservoir, (**d**) detection reservoir

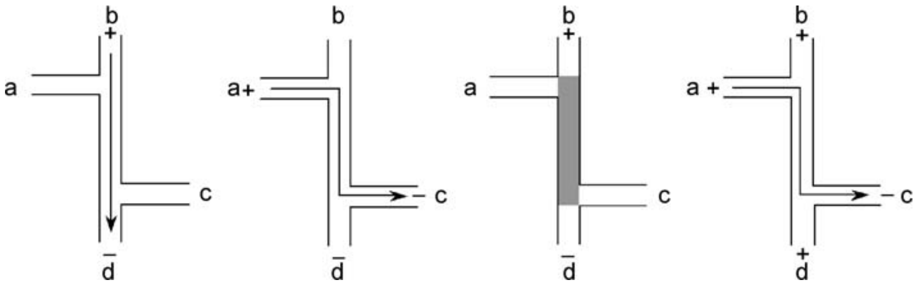
reservoirs floated. The separation was usually performed by applying a separation voltage to the running buffer reservoir (Fig. 1b) with the detection reservoir grounded and other reservoirs floating. This technique is characterized by ease of control and variation of injected volume and is suitable for continuous and sequential injection for on-line measurements. This approach to sample introduction may suffer from uncontrolled dispersion, resulting in irreproducible injection volumes. The electrokinetic biasing of the sample is another major problem of this method. The injected sample may not be representative of the whole sample. Time-based injections involve applying an electric field to move the sample continuously at a known flow rate, for a given period of time into the reaction or separation channels.

The volume-based sample introduction can be further classified into floating and pinched modes. The volume-based floating injection method applies a high voltage across the sample line only, leaving all the other channels and reservoirs floating. The high voltage is applied to the sample channel (ac) (see Figs. 2a – 2c) to pump the sample solution by EOF to fill the intersections. However, no voltage is applied between reservoirs (b) and (d) so that leakage and migration of the sample solution into the separation channel during injection will occur, resulting in uncontrollable injection volumes. This floating sample introduction technique is quite simple since it only requires one high voltage. When the sample zone passes across the intersection, the sample will migrate toward both (b) and (d) due to the diffusion and eddy effects. Separation can be carried out by switching the electric field to run in the direction of (b) and (d). The sample plug in the intersection will move towards (d) and is separated in the separation channel. To prevent leakage and diffusion of the sample solution, a *pinched* injection method has been developed while an electric field is applied to every channel within the microfluidic chip system. Typically, an electric field (ac) is applied across the sample channel as shown in Fig. 2d, thus moving the sample to fill the intersection. Meanwhile, a lower positive potential will be applied to all the other reservoirs to keep the sample solutions pinched so as to reduce, or preferably eliminate, leakage from the sample into the side channels (see Fig. 2d). And then, the electric field is re-directed so that (d) in Fig. 2d is grounded, with all the other channels positive relative to (d) in Fig. 2d for separation. Jacobson et al. [2] have demonstrated that an improvement in RSD values from 2.7% to 1.7% for a 90-pl injection volume could be obtained using the pinched method compared to that achieved using the floating method. The much higher reproducibility of pinched injection than time-based injection and the minimization of the diffusion/leakage at the intersections offer great promise for microfluidic chips.

Pressure injection is another important technique for transferring samples to microfluidic chips. ►Positive pressure or suction (vacuum) pressure is used to generate a pressure difference to the reservoir on the chips and drives the sample solution into the microchannel. The main advantage of pressure injection over the electrokinetic injection mentioned above is the lack of electric discrimination resulting from the different ion mobilities. But it is unsuitable for gel-filled capillaries. Due to the low dimensions of the micochannels in chips, pumping mechanisms usually lead to high backpressure and the conventional parabolic flow, resulting in band broadening and the dilution of the sample. The amount of sample transferred to the chips has to be calculated, considering the sample viscosity, injection time, and pressure differential. The precision of the injection is difficult to control because the atmospheric conditions and elevation affect the pressure differences and the amount of samples being transferred.

Samples are usually manually loaded into the sample reservoir using standard pipettors and their replacement requires extensive washing. Such manual or automated sample removal limits the sampling rate and is incompatible with the high performance of microchip devices.

T



Transferring Samples to Chips, Techniques, Figure 2 Operation processes of (**a–c**) volume-based floating injection and (**d**) pinched injection: (**a**) sample reservoir, (**b**) running buffer reservoir, (**c**) unused reservoir, (**d**) detection reservoir

Efficient assays of real-world samples will require the incorporation of a continuous sampling capability (from the external environment) or rapid sampling of multiple discrete samples. Such ability to continuously introduce real samples into micrometer channels would make *Lab-on-a-Chip* devices compatible with real-life applications. Despite various approaches proposed recently for transferring samples to microchips, the "world-to-chip" interface remains a major barrier for real-life applications of microchip devices.

Key Research Findings

Fang et al. [3] have developed a high-throughput continuous sample-transfer interface for microfluidic chip-based capillary electrophoresis systems. A world-to-chip interface has been fabricated based on a novel flow-through sampling reservoir with a guided overflow design. The flow-through reservoir was fabricated on a glass microchip of crossed-channel design used for CE separations. The 20-μl sample reservoir was produced from a plastic pipette tip and fixed at one end of the sampling channel. Sample change was performed by pumping samples, sandwiched between air segments, through the flow-through reservoir, introduced from an access hole on the bottom side of the chip. A filter paper wrapped tightly around the reservoir guided the overflowing sample solution into a plastic trough surrounding the reservoir and then to waste. The feasibility and performance of the novel system was demonstrated by the determination of arginine, glycine, phenylalanine, and glutamic acid, by continuously introducing a train of different samples through the system without electrical interruption. Maximum throughputs of 80/h were achieved with $<4.1\,\%$ carryover and precisions of 1.5% for arginine and 2.6 % RSD for glycine ($n = 11$) when employing a separation channel of 4 cm (2-cm effective separation length) and a separation voltage of 1.4 kV. The sampling system was tested by continuous monitoring of the derivatization of amino acids over a period of 4 h, involving 166 analytical cycles. There was an outstanding overall precision of 4.8 % RSD ($n = 166$).

Solignac and Gijs [4] have presented a simple capillary electrophoresis microsystem in which the sample is injected hydrodynamically using a pressure pulse. This approach can transfer a sample solution without electric bias, in contrast to a classical electrokinetic injection, in which the magnitude of the electric field in the sample reservoir in combination with variations in electrophoretic mobility can lead to a biased injection. The sample can be loaded using a well controlled and variable pressure pulse ($0.1-1.0$ s) generated by the mechanical actuation of a flexible membrane placed on the sample reservoir of the chip. A fluorescein/calcein-containing borate-tris-hydroxymethylaminoethane (TRIS) sample solution has been taken as a model system for CE analysis. The separation results using pressure pulse injection clearly demonstrate the advantages of this approach. In addition to the reduced bias due to the absence of an electrode in the sample well, this method allows the injection of variable plug volumes by simply changing the pulse length. Figure 3 is a schematic diagram of the cylindrical reservoir used for the pulsed pressure injection. It is identical to a reservoir used with electrodes for electrokinetic pumping, but contains no electrode and is covered by a PDMS membrane that is applied on the top of the reservoir after filling it, but is not firmly bonded to it. This membrane is mechanically actuated with an electromagnet fixed on a linear translation stage. The actuator exerts a mechanical deformation of the membrane (as illustrated in Fig. 3), and provokes a momentary pressure rise within the reservoir. The PDMS membrane provides a good seal with the sample reservoir under pressure. When the membrane is deflected, the pressurized air pushes the liquid in the injection channel. The injection involves small quantities of liquid. The volume flushed into the injection channel is below 0.2 μl, as compared to the 36-μl sample reservoir volume. The pressure is released when the actuator returns to its initial position (after a variable time of $0.1-1.0$ s) using the backforce of a spring. They purposely used a flexible membrane to avoid or strongly reduce "backsucking" from the injection channel.

Most of the sample-transfer methods for microfluidic chips described above have been used to either inject discrete samples into a separation lane on a microchip or perform repeated injections of a single sample. Between

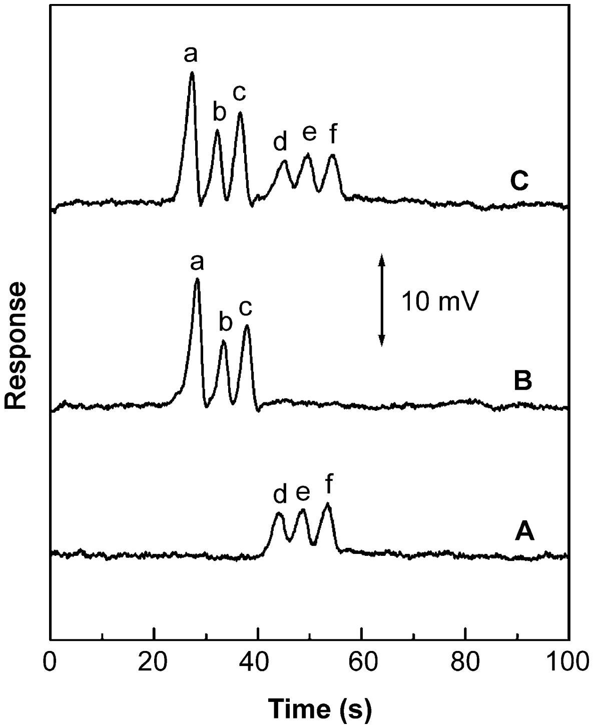
Transferring Samples to Chips, Techniques, Figure 4 A novel flow-through sampling design for continuous sampling on an electrophoresis-based microchip, in which electrical voltages are applied to the electrophoretic channels to control sample loading for separation and detection as well as to inhibit sample leakage. (Reproduced with permission from [5])

analyses of different samples, the reservoirs and channels have often been washed manually and new samples have been placed in the sample reservoirs. This has hindered the realization of high throughput even when very fast separations are achieved on microchips. An attempt must be made to match the amount of time it takes to load the samples into the chip with the high-efficiency characteristic of these microchip devices. Various methods have been developed to transfer samples from the macroworld to a microchip in order to improve the separation throughput and achieve continuous analysis. Chen et al. [5] have proposed a method for the operation of a flow-through sampling chip and its application for immuno-separation, as well as its integration with a wash/elution bed for protein purification, concentration, and detection. This novel device used hydrodynamic pressure to drive the sample flow, and a gating voltage was applied to the electrophoretic channel on the microchip to control the sample loading for the separation and to inhibit sample leakage. Figure 4 illustrates the voltage-switching scheme for this sampling microchip. A high positive voltage, regarded as the gating voltage, was applied to reservoir E while reservoirs D and F were grounded (Fig. 4 (a)). Under this voltage scheme, the inlet flow was split at the first intersection and then directed to reservoir D through the second intersection. For sample loading (Fig. 4 (b)), reservoirs D–F were floating for a specified period that determined the amount of sample transferred to the separation channel. For sample separation (Fig. 4 (c)), reservoirs D and F were immediately grounded and the separation voltage was applied to reservoir E to initiate the electrophoretic separation. Use of this device requires optimization of the gating voltage as a function of the hydrodynamic flow rate. The function of the flow-through sampling microchip has been demonstrated by separation of Cy5-labeled bovine serum albumin (Cy5-BSA) and its antibody complex.

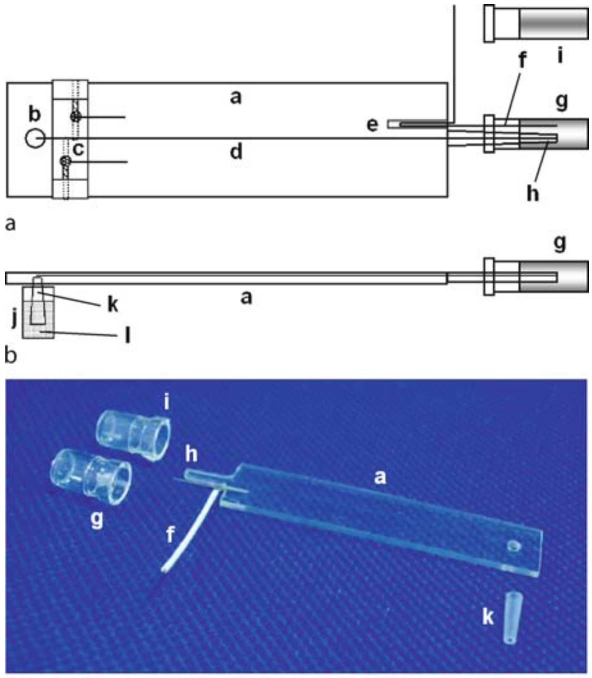
Wang et al. [6] have fabricated a novel dual-injection electrophoretic poly(methylmethacrylate) (PMMA) microchip. It consists of two crosses on both sides of the chip and one separation channel. Anions and cations can be injected electrokinetically from both crosses to the separation channel and then be simultaneously separated and detected. A movable contactless conductivity detector was put along the separation channel between the two crosses to detect the ions. The feasibility, utility, and advantage of this new system has been demonstrated by injecting, separating, and detecting ammonium, methyl ammonium, sodium, chloride, nitrate, and perchlorate (six ionic explosives) simultaneously. This versatile chip can also be used to separate anions or cations alone. The simultaneous detection of anionic and cationic explosives and nerve agent degradation products by the newly designed

chip has also been demonstrated. The attractive properties of the dual-injection chip will find a wide range of other applications in the life sciences, environmental analysis, etc. Figure 5 shows the electropherograms for a mixture solution containing 2 mM ammonium (a), 1 mM methyl ammonium (b), 1 mM sodium (c), 1 mM chloride (d), 1 mM nitrate (e), and 1 mM perchlorate (f) introduced by cathodic injection (A), anodic injection (B), and dual injection (C). As shown in Fig. 5C, six ions were baseline separated by the dual-injection chip after the simultaneous injection. Electropherograms A and B correspond to the detection of the anions alone (via cathodic injection) and of the cations alone (via anodic injection), respectively. In this case, the injection method was changed from the dual-injection described above. It can be seen that the profiles of the single-injection electropherograms of the anions and cations, shown in Fig. 5 (A and B, respectively), are comparable to the corresponding peaks in the combined dual cathodic/anodic injection response (C). Such a microchip layout is therefore very versatile as it offers three operation modes (i. e., anode, cathode, and dual detection corresponding to measurements of the cations, anions, and both, respectively). The change between these modes can be carried out by simply switching the high voltages.

Chen et al. [7] have developed a new CE system based on a PMMA electrophoretic microchip with an easy sample-introduction interface. One side of the PMMA chip was sharpened to fabricate a sharp inlet tip, allowing rapid and reproducible sample introduction into CE microchip devices coupled to contactless conductivity detection. The new microfluidic interface relies on the use of a sharp sample-inlet tip placed alternately in the sample and buffer vials. This design facilitates the electrokinetic introduction of discrete samples directly into the separation microchannel without the use of injection crosses and allows rapid replacement of different samples. One side of the microchip was cut to leave a separation channel (Fig. 6 (see (d)). The hole (b) near the detection point could accommodate the pipette tip (k), allowing the solution connection between the separation channel (d) and the buffer reservoir (j). A 0.8-mm diameter hole (e) was drilled beside the sharp tip to accommodate the Pt high-voltage electrode (f). Figure 6c shows a photograph of the final PMMA microchip with a sharp inlet tip. The sample solution was introduced into the channel by applying the desired potential between the *sample* vial (i) and the buffer reservoir (j) for 2 s. Subsequently, the inlet tip (Fig. 6 (see (h)) was immersed into the running buffer vial (Fig. 6 (see (g)) and the separation voltage was applied between points (g) and (j) in Fig. 6. The high voltage was commonly applied for 2 s after placing the inlet tip in the sample or buffer vials and was disconnected for 3 s before removing the tip from the corresponding vial. The high voltage was disconnected during sample or running buffer change. The solutions in the vials (Fig. 6 (see (g) and (i)) were retained by the surface tension although the orientation of the vial mouths was horizontal. The new sharp-chip design facilitates the analysis of multiple discrete samples through a simplified electrokinetic introduction of highly reproducible sample zones (Fig. 6). Such introduction is carried out directly in the separation channel (without an injection cross) by alternate placement of the inlet tip in vials containing the sample or buffer solutions. This sample introduction results in the insertion of highly reproducible sample plugs and allows rapid replacement of different samples with no apparent carry carry-over because PMMA is hydrophobic. In the case of high concentration samples, the unwanted sample carry-over can be minimized by immersing the inlet tip (Fig. 6 (see (h)) in



Transferring Samples to Chips, Techniques, Figure 5 Electropherograms for a mixture solution containing 2 mM ammonium (a), 1 mM methyl ammonium (b), 1 mM sodium (c), 1 mM chloride (d), 1 mM nitrate (e), and 1 mM perchlorate (f) introduced by cathodic injection (A), anodic injection (B), and dual injection (C). Operation conditions: separation voltage, +1000 V; injection voltage, +500 V; injection time, 1s; running buffer, 20 mM MES-20 mM His (pH 6.1); sinus waveform with frequency of 200 kHz and a peak-to-peak voltage of 10 V. (Reproduced with permission from [6])



Transferring Samples to Chips, Techniques, Figure 6 (**a**) Top, and (**b**) side view of a PMMA electrophoresis microchip with a sharp-tip inlet (h) and a movable electrode system (c) for the contactless conductivity detection and (**c**) a photograph of the final PMMA microchip with a sharp inlet tip. Transferring Samples to Chips, Techniques, Figure 7 Electropherograms for a mixtures containing 1mM potassium (a), 1mM sodium (b), and 1mM lithium (c) at the separation of voltages of (A) +500, (B) +1000, (C) +1500, (D) +2000, and (E) +2500V. Also shown (in the inset) are the resulting plots of the dependence of the plate numbers (*N*) of (c) and the resolution (*R*) between (a) and (b) upon the separation voltage. Operation conditions: injection voltage, +1000V; injection time, 2s; running buffer, 20mM boric acid-20mM TRIS (pH 8.0); sinus waveform with a frequency of 200kHz and a peak-to-peak voltage of 5V; electrode distance, 0.8mm; electrode width, 0.8mm. (Reproduced with permission from [6])

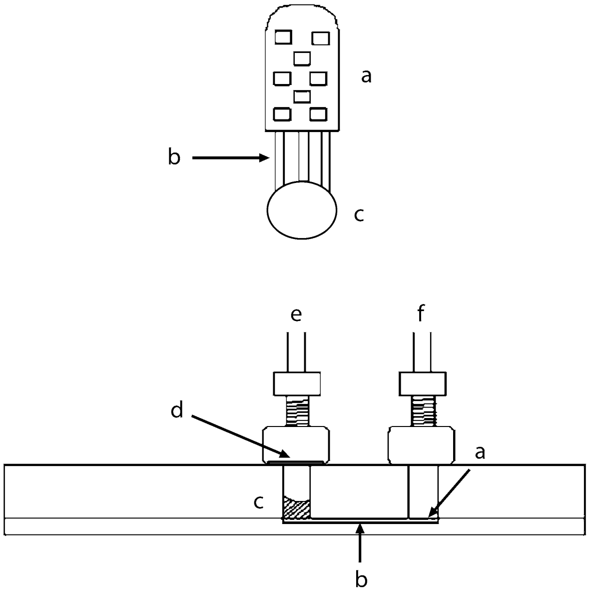
a cleaning vial containing the running buffer for 1 – 2 s before placing the tip in the buffer vial (Fig. 6 (see (g)) for the electrophoretic separation. Figure 7 shows the electropherograms for a mixtures containing 1 mM potassium (a), 1 mM sodium (b), and 1 mM lithium (c) at the separation of voltages of (A) +500, (B) +1000, (C) +1500, (D) +2000, and (E) +2500 V by using the sharp tip microchip. As expected, increasing the separation voltage from +500 to +2500 V (A-E) dramatically decreases the migration time, from 99.6 to 21.1 s, from 140.4 to 29.1 s, and from 174.5 to 36.2 s for potassium (a), sodium (b), and lithium (c), respectively. The inset of Fig. 7 shows the effects of the separation voltage upon the plate number (N/m^{-1}) of lithium (c) and the resolution (R) between potassium (a) and sodium (b). The plots for both N and R versus the separation voltage have the similar profiles. Upon raising the separation voltage between +1000 and +2500 V, N and R increase to the maximum values of 44,814 m^{-1} and 2.6 (at +1500) and decrease gradually to 28,005 m^{-1} and 1.8, respectively. Despite the higher separation voltage, flat baselines and low noise levels are maintained even at high separation voltages. Such behavior indicates an effective isolation from the high separation voltage.

Takabayashi et al. [8] have described the development of a microchip for the detection of nitrogen dioxide (NO_2, a gaseous chemical pollutant) in air. A quartz glass microchip has been fabricated for handling the following three functions: gas absorption, chemical reaction, and fluorescence detection. Channels constructed in the microchip were covered with porous glass plates, allowing nitrogen dioxide to penetrate into the triethanolamine (TEA) flowing within the microchannel beneath. The nitrogen dioxide was then mixed with TEA and reacted with a fluorescence reagent in the chemical reaction chamber in the microchip. The reacted solution was then allowed to flow into the fluorescence detection area to be excited by an ultraviolet light-emitting diode, and the flu-

orescence was detected using a photomultiplier tube. Preliminary studies with standardized test solutions revealed quantitative measurements of nitrite ion (NO_2^-), which corresponded to atmospheric nitrogen dioxide in the range of 10 – 80 ppb.

Kobayashi et al. [9] have developed an efficient system for tri-phase reactions using a microchannel reactor. They conducted hydrogenation reactions that proceeded smoothly to afford the desired products quantitatively within 2 min for a variety of substrates. The hydrogen gas was transferred to the microfluidic channel by pressure and was allowed to interact with the liquid substrates and the solid catalyst. They could achieve an effective interaction between hydrogen, substrates, and a palladium catalyst using the extremely large interfacial areas and the short path required for molecular diffusion in the very narrow channel space. This concept could be extended to other multiphase reactions that use gas-phase reagents such as oxygen and carbon dioxide.

Recently, a glass microimpinger on microchip for gas phase sampling of hydrogen cyanide has been designed and fabricated by Tipple et al. [10]. A microimpinger consisting of a gas sample inlet, gas delivery arms, and an extraction reservoir was fabricated using standard glass microfabrication techniques to extract dilute hydrogen cyanide vapor from a gas delivery system using a basic aqueous trapping buffer. A Teflon membrane was used to contain the liquid sample in the extraction reservoir. The extraction efficiency for sampling the hydrogen cyanide was monitored by forming a fluorescent cyanide isoindole in the reaction of cyanide with naphthalene-2,3-dicarboxaldehyde and taurine. It has been demonstrated that a microfabricated and miniaturized glass impinger could be used as a gas-sampling device on a Lab-on-a-Chip platform. This glass microimpinger relies on the vacuum sampling of gaseous analytes through an extraction solution, much like a traditional impinger. The feasibility and operability of this microimpinger was characterized with regards to hydrogen cyanide vapor sampling. Figure 8 shows the top and side views of the glass microimpinger design. The width and length of the arms extending from the gas sample inlet into the extraction reservoir (Fig. 8 (b)) were 250 μm and 3.5 mm, respectively. These channels were 20 μm deep. The length and width of the gas sample inlet were 6.2 and 3.1 mm, respectively. The small squares shown in the gas sample inlet ($353 \times 353\,\mu m^2$) were intentionally placed in this region to both aid in the further mixing of the diluted cyanide vapor and to provide structural stability to the region during the bonding process. The diameter of the extraction reservoir was 2.10 mm. This diameter and the thickness of the cover plate (5.5 mm) created a reservoir with a total volume of approximately 20 μl.



Transferring Samples to Chips, Techniques, Figure 8 Schematic illustration of the glass microimpinger used in these studies. The upper drawing shows a top view layout of: (a) the gas sample inlet, (b) the impinger arms, and (c) the extraction reservoir. The lower drawing shows the side view and the placement of: (d) the Teflon membrane, and the tubing connections (e) for the vacuum pump, and (f) from the gas delivery system. Future Directions for Research

Techniques for transferring samples to microchips play a key role in the microchip-based system. Future directions for sample introduction will focus on the automation of the sample transfer to the microchips, the development of the world-to-chip interface for real-life applications, the integration of the sample pre-treatment unit and sample-introduction interfaces, the direct introduction of ► gaseous samples, and various designs for sample introduction. With the rapid development of microfluidic chips, it is highly desirable to develop new theoretical models, experimental methods, and new experimental devices for transferring samples to chips.

Transition to Turbulence in Microchannels

Satish G. Kandlikar

Synonyms

Laminar to turbulent flow transition; Critical Reynolds number

Definition

Transition from laminar to turbulent flow is identified by a departure from the laminar flow velocity profile, and the presence of time-varying velocity component in the flow, especially near the wall. The wall shear stress becomes higher following the departure from the laminar flow. The transition occurs over a range of Reynolds number, and is dependent on the local wall and flow conditions. Microchannels are defined as channels with the minimum channel dimension in the range from 1 – 200 μm [1].

Overview

Transition to turbulence is the result of localized flow instabilities. As the Reynolds number increases, these instabilities are set in at the wall. The instabilities are also created as a result of the wall roughness or specific structural features present on the wall, such as grooves, ridges and other roughness elements. At Reynolds numbers below the transition value, the instabilities generated are overcome by the flow inertia, and the *relaminarization* process causes the flow to revert back to laminar flow [2]. At higher Reynolds numbers, the instabilities near the wall are propagated into the flow and transition to turbulent

flow occurs. The transition has been linked to the Reynolds number based on the average shear stress Re_τ, [3]:

$$\mathrm{Re}_\tau = \frac{H/2}{\upsilon}\sqrt{\frac{\tau_{\mathrm{w,av}}}{\rho}} > 40 - 60 \qquad (1)$$

Where H is the channel height (the smaller dimension in a rectangular channel), $\tau_{\mathrm{w,av}}$ the average wall shear stress, υ the kinematic viscosity, and ρ the density of the fluid. In internal flows, the laminar to turbulent transition in abrupt entrance rectangular ducts was found to occur at a transition Reynolds number $\mathrm{Re_t} = 2200$ for an aspect ratio $\alpha_c = 1$ (square ducts), to $\mathrm{Re_t} = 2500$ for flow between parallel planes with $\alpha_c = 0$ [4]. For intermediate channel aspect ratios, a linear interpolation is recommended. For circular tubes, $\mathrm{Re_t} = 2300$ is suggested. These transition Reynolds number values are obtained from experimental observations in smooth channels in macroscale applications of 3 mm or larger hydraulic diameters. Their applicability to microchannel flows is still an open question.

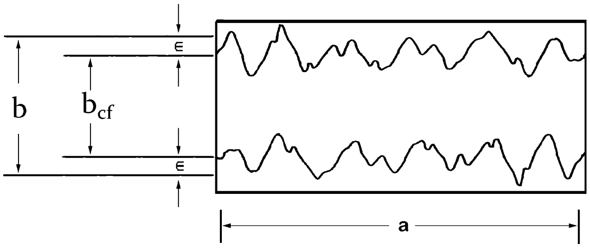
Basic Methodology

The transition to turbulence is generally identified by conducting experiments to measure local pressure variation along the length of a tube and estimating the local friction factor value. The local friction factor is then used as an indicator of the type of the flow. Transition from laminar to turbulent flow is identified by noting the departure from the laminar flow friction factor values. As the transition sets in, the friction factor increases above the laminar flow value. Care needs to be taken in ascertaining that the entrance region effects are accounted for properly.

Key Research Findings

Although a number of researchers in 1990s have suggested that the transition to turbulence occurs at lower Reynolds numbers, some of the recent experiments conducted under careful conditions [5–7] have shown that for smooth microchannels, the transition Reynolds number remains the same as for the macroscale channels.

The transitions observed at lower Reynolds numbers are due to the presence of roughness on the wall surface. In order to study the effect of roughness on transition to turbulence, a systematic experimental study was conducted by Kandlikar et al. [7]. A test fixture was developed with 10 mm wide channels, and an adjustable gap to allow for different channel sizes. The two side walls were removable, and different surface features could be machined on them. For smooth channels, the transition was noted to occur between $\mathrm{Re_t} = 2300$ and $\mathrm{Re_t} = 2500$.



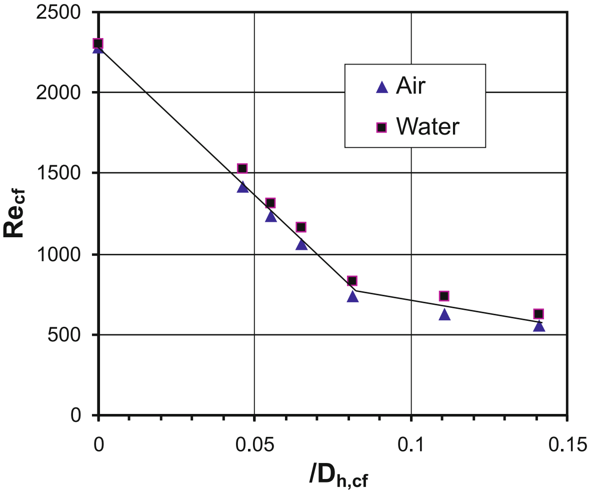
Transition to Turbulence in Microchannels, Figure 1 Geometry of a rough rectangular channel

Different roughness features were introduced by machining ridges onto the walls. As the relative roughness ($= \varepsilon/\mathrm{D_{h,cf}}$) increased, the transition was observed to occur at lower Reynolds numbers. The hydraulic diameter $\mathrm{D_{h,cf}}$ was based on the constricted flow dimensions (representing the free flow area in the channel). Thus for a rectangular channel, shown in Fig. 1, with the long walls having a roughness height of ε, the constricted channel height b_{cf} is expressed in terms of the maximum height of the channel from the base of one wall to the base of the other wall, b, by the following equation:

$$b_{\mathrm{cf}} = b - 2\varepsilon \qquad (2)$$

Figure 2 shows the variation of the transition Reynolds number as a function of $\varepsilon/\mathrm{D_{h,cf}}$. It is observed that for $\varepsilon/\mathrm{D_{h,cf}} = 0.1$, or 10%, the transition Reynolds number is estimated to be as low 700 [7, 10].

The representation of surface roughness itself is an important subject. Taylor et al. [8] provide a detailed descrip-



Transition to Turbulence in Microchannels, Figure 2 Variation of transition Reynolds number with relative roughness based on constricted flow diameter, adapted from [7, 10]

tion of various roughness parameters used to represent the roughness of a surface forming the walls of a channel. The traditional roughness parameter Ra was shown to be inadequate as two surfaces with very different surface features, such as ridge heights and pitches, may yield the same Ra, but their fluid flow performance is entirely different. Further details of the specific roughness parameter can be found in [8] and [9].

Future Directions for Research

Since the channel dimensions in a microchannels are less than 200 μm, a roughness height of only several micrometers results in a relative roughness that is sufficient to cause a departure from the flow in smooth channels. The turbulent flow may be desirable in microchannels to enhance the transport processes, such as heat transfer or mass transfer at the wall. It is therefore possible to design microchannels that can effectively use the higher thermal performance characteristics in the turbulent flow. It is essential to keep a watch on the resulting pressure drop. In general, suitable header design will be able to provide a pressure drop that is within an allowable limit.

Mixing in microchannels in another major application where the transition to turbulent flows can be utilized for enhanced mixing possible in turbulent flows. The roughness elements then act to destabilize the flow and induce local instabilities. The localized transition to turbulence will enhance the mixing, and relaminarization process downstream will provide the laminar flow with its lower friction factor and associated lower pressure drop penalties.

Transmittance

Definition

Transmission is the term used to describe the process by which incident radiant flux leaves a surface or medium from a side other than the incident side, usually the opposite one. The transmittance is the ratio of the radiant flux after it has traversed a surface or medium to its incident flux, often expressed in percentage.

nadim@kgi.edu

Synonyms

Acoustic droplet ejection; Acoustic levitation of droplets; Droplet transport by surface acoustic waves; Radiation pressure; Surface acoustic waves; Acoustic particle concentration; Droplet manipulation; Drop on demand

Definition

Transport of droplets by acoustics refers to the use of acoustic or ultrasonic waves in fluids or on solid surfaces to generate, manipulate, position or transport liquid droplets, ranging from picoliters to microliters in volume, surrounded by a gas or immiscible liquid phase and/or attached to a solid surface.

Overview

Acoustic waves in liquids can give rise to so-called radiation pressure forces that can in turn drive acoustic streaming flows, deform fluid–fluid interfaces to generate droplets, or exert levitation forces on suspended drops or particles. This contribution reviews three technologically relevant examples of these effects: acoustic droplet ejection, droplet transport along a solid surface using surface acoustic waves, and acoustic levitation of droplets.

Acoustic droplet ejection refers to the process whereby a focused acoustic beam directed toward a liquid–air interface can cause the ejection of discrete droplets of the liquid. Use of surface acoustic waves (SAW) on a solid upon which sessile droplets are attached can cause the migration of those droplets along the solid surface. Finally, standing acoustic waves in flow channels can be used to exert levitation forces on suspended droplets or particles in the channel, causing them to concentrate along a line, which can be applied to sheathless focusing in flow cytometry.

In order to understand the physical underpinnings of the above processes and to be able to model them mathematically, we begin by providing an overview of the relevant concepts from fluid dynamics and acoustics. This is followed by a separate discussion of each of the above applications.

Basic Methodology

In this section, the equations governing acoustic waves in fluids and surface waves in solids are described and concepts from nonlinear acoustics such as radiation pressure and acoustic streaming are reviewed in order to provide an appropriate framework for modeling and simulation of droplet transport by acoustics.

Governing Equations

The equations that govern acoustic waves in an ideal (inviscid) fluid consist of the conservation of mass and linear momentum equations

$$\frac{\partial \rho}{\partial t} + \nabla \cdot (\rho \boldsymbol{v}) = 0\,, \tag{1}$$

$$\frac{\partial (\rho \boldsymbol{v})}{\partial t} + \nabla \cdot (\rho \boldsymbol{v}\boldsymbol{v}) = -\nabla p\,, \tag{2}$$

in which $\rho(\boldsymbol{x}, t)$, $p(\boldsymbol{x}, t)$ and $\boldsymbol{v}(\boldsymbol{x}, t)$ are the density, pressure and velocity fields, respectively, t is time and $\boldsymbol{x}$ is the position vector. In addition, an equation of state (EOS) that relates the pressure and density fields is needed. Since it is usually the case that the fluid remains isentropic during small-amplitude sound propagation, an adiabatic equation of state is generally assumed, in the form [1]:

$$p - p_0 = Q_0 \left[\left(\frac{\rho}{\rho_0} \right)^{\gamma} - 1 \right], \tag{3}$$

where p_0 and ρ_0 are the base pressure and density, respectively, $Q_0 = \rho_0 c_0^2 / \gamma$ and c_0 is the small-signal speed of sound. In an ideal gas, γ is the ratio of the constant-pressure to constant-volume specific heat capacities and $c_0 = \sqrt{\gamma p_0/\rho_0}$, for which Eq. (3) reduces to $p/p_0 = (\rho/\rho_0)^{\gamma}$. For liquids, γ is an empirical parameter and Eq. (3) is known as the Tait equation. For water, $\gamma \approx 7$ and $Q_0 \approx 3000$ bars [1].

Linear Acoustics

Linearization of Eqs. (1)–(3) can be effected by writing the density, pressure and velocity fields as:

$$\rho - \rho_0 = \rho_1 + \rho_2 + \cdots \tag{4}$$

$$p - p_0 = p_1 + p_2 + \cdots \tag{5}$$

$$\boldsymbol{v} = \boldsymbol{v}_1 + \boldsymbol{v}_2 + \cdots \tag{6}$$

in which quantities with subscript '1' are the leading-order perturbations from the base state (referred to as the 'acoustic' fields), with quantities having subscript '2' or higher being successively smaller. Note that it is assumed that the

fluid in the base state is quiescent, so the leading term in the velocity field is due to the linear acoustic signal.

Substitution of expansions (4)–(6) into the governing conservation equations and the EOS and retention of leading terms results in the equations of linear acoustics in the form:

$$\frac{\partial \rho_1}{\partial t} + \rho_0 \nabla \cdot \boldsymbol{v}_1 = 0\,, \tag{7}$$

$$\rho_0 \frac{\partial \boldsymbol{v}_1}{\partial t} + \nabla p_1 = \boldsymbol{0}\,, \tag{8}$$

$$p_1 = c_0^2\, \rho_1\,. \tag{9}$$

Upon taking the partial time derivative of Eq. (7), subtracting the divergence of Eq. (8) from the result and making use of the linearized equation of state (9), the acoustic pressure field is seen to satisfy the linear wave equation:

$$\frac{\partial^2 p_1}{\partial t^2} = c_0^2 \nabla^2 p_1\,. \tag{10}$$

Indeed, the same equation is also satisfied by the density field ρ_1, the velocity field $\boldsymbol{v}_1$ and the velocity potential ϕ_1. The latter may be introduced by noting that for irrotational flows where $\nabla \times \boldsymbol{v} = \boldsymbol{0}$, the velocity derives from a potential: $\boldsymbol{v} = \nabla\phi$.

In the framework of linear acoustics, one can also derive an equation for conservation of *acoustic energy* which involves quadratic terms in the primary acoustic disturbances. That equation is given by [2]:

$$\frac{\partial w}{\partial t} + \nabla \cdot \boldsymbol{I} = 0\,, \tag{11}$$

where the acoustic energy density w and the acoustic intensity vector $\boldsymbol{I}$ are given by

$$w = \frac{p_1^2}{2\rho_0 c_0^2} + \frac{\rho_0 \boldsymbol{v}_1^2}{2}\,, \quad \boldsymbol{I} = p_1 \boldsymbol{v}_1\,, \tag{12}$$

in which $\boldsymbol{v}_1^2 = \boldsymbol{v}_1 \cdot \boldsymbol{v}_1$.

Plane Waves

Starting with the equations of linear acoustics, useful relationships among the variables can be obtained for the case of so-called plane waves [2] propagating in infinite space in a particular direction. If the unit vector in the direction of plane wave propagation is denoted by $\hat{\boldsymbol{n}}$, with the acoustic pressure field of the plane wave given by

$$p_1(\boldsymbol{x}, t) = f(t - \hat{\boldsymbol{n}} \cdot \boldsymbol{x}/c_0)\,, \tag{13}$$

the acoustic velocity and density fields would then be given by [2]:

$$\boldsymbol{v}_1 = \hat{\boldsymbol{n}} \frac{p_1}{\rho_0 c_0}\,, \quad \rho_1 = \frac{p_1}{c_0^2}\,. \tag{14}$$

Note that f can be an arbitrary function of its scalar argument and the above would satisfy the equations of linear acoustics. For instance, for propagation along the x-direction in a Cartesian coordinate system, right-going pressure waves of the form $p_1 = f(x - c_0 t)$ produce a velocity of the form $\boldsymbol{v}_1 = \hat{\boldsymbol{i}}\, p_1/(\rho_0 c_0)$, whereas left-going pressure waves of the form $p_1 = g(x + c_0 t)$ lead to the velocity $\boldsymbol{v}_1 = -\hat{\boldsymbol{i}} p_1/(\rho_0 c_0)$. Here, $\hat{\boldsymbol{i}}$ is the unit vector in the increasing x direction. This becomes an important distinction when the problem of reflection and transmission of a wave across an interface between two media is considered. It is also seen that the product of fluid density and sound speed, $\rho_0 c_0$, provides the proportionality between pressure and speed. This combination occurs frequently in acoustics and is known as the *acoustic impedance*.

The acoustic energy density and intensity vector for a plane wave are given by

$$w = \rho_0 \boldsymbol{v}_1^2 = \frac{p_1^2}{\rho_0 c_0^2}\,, \quad \boldsymbol{I} = \hat{\boldsymbol{n}} \frac{p_1^2}{\rho_0 c_0} = \hat{\boldsymbol{n}}\, c_0 w\,. \tag{15}$$

Radiation Pressure

Acoustic waves in fluids are often characterized by time-periodic oscillations of a given radian frequency $\omega = 2\pi f$ (with f the frequency in cycles per unit time) at any given point in space. As such, time-averages over one period of the oscillation $T = 2\pi/\omega = f^{-1}$ of linear quantities are zero, whereas averages of quadratic quantities over time produce non-zero means. Denoting the time-average over one period by $\langle\cdot\rangle$ and applying this operator to the original momentum conservation equation (2) yields [1]:

$$\nabla \cdot \Pi = \boldsymbol{0}\,, \tag{16}$$

where Π is the acoustic radiation stress tensor

$$\Pi = -\langle p\rangle\, \boldsymbol{\delta} - \langle \rho \boldsymbol{v}\boldsymbol{v}\rangle \approx -\langle p - p_0\rangle\, \boldsymbol{\delta} - \rho_0 \langle \boldsymbol{v}\boldsymbol{v}\rangle\,. \tag{17}$$

To arrive at these results, we have noted that the time-average of the leading partial time-derivative in Eq. (2) is zero and that, since the velocity field is already a first-order quantity (with the base state being one of zero flow), the acoustic stress is correct to second order as written on the far right-hand side of Eq. (17). Here, $\boldsymbol{\delta}$

T

denotes the unit isotropic tensor of rank two whose components in a Cartesian system are given by the Kronecker delta symbol δ_{ij}. That is, in component form, $\Pi_{ij} = -\langle p - p_0 \rangle \delta_{ij} - \rho_0 \langle v_i v_j \rangle$.

The quantity $\langle p - p_0 \rangle$ in Eq. (17) is the *mean excess pressure* and in general, it is nonzero for finite amplitude waves. It is also an *Eulerian* quantity since the time-averaging is being performed at a fixed position in space. Wang and Lee [1] provide a succinct derivation for the value of this Eulerian mean excess pressure, correct to second order but expressed in terms of first-order quantities, in the form:

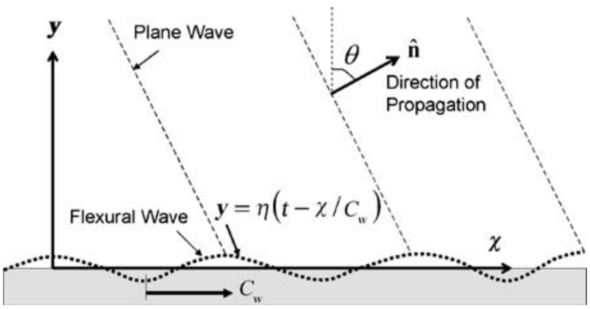
$$\left\langle p^{\mathrm{E}} - p \right\rangle = \frac{1}{2\rho_0 c_0^2} \left\langle p_1^2 \right\rangle - \frac{1}{2}\rho_0 \left\langle v_1^2 \right\rangle + C$$
$$= \langle V \rangle - \langle K \rangle + C\,. \tag{18}$$

The superscript 'E' is affixed to pressure as a reminder of its Eulerian nature, and $\langle V \rangle = \langle p_1^2 \rangle / 2\rho_0 c_0^2$ and $\langle K \rangle = \rho_0 \langle v_1^2 \rangle / 2$ are the time-averaged potential and kinetic energy densities, respectively. Constant C is independent of both space and time; in linear acoustics it is zero, but at second order, it is sometimes needed to satisfy a constraint such as constancy of total mass or the condition of having no perturbation at infinity.

One can also calculate a *Lagrangian* mean excess pressure by time-averaging the pressure of a material fluid particle which oscillates in space during the passage of the acoustic wave. That pressure, designated by superscript 'L', can be shown to take the form [1]:

$$\left\langle p^{\mathrm{L}} - p \right\rangle = \langle V \rangle + \langle K \rangle + C = \langle w \rangle + C\,, \tag{19}$$

where the acoustic energy density w is defined in Eq. (12).



Transport of Droplets by Acoustics, Figure 1 Schematic representation of launching of plane waves in a fluid by small-amplitude traveling flexural waves on a wall. The flexural wave speed c_{W} must be supersonic with respect to the speed of sound c_0 in the fluid for such plane waves to be generated. If the flexural wave is subsonic, the disturbance dies out exponentially with y

Wang and Lee [1] define the so-called Langevin and Rayleigh radiation pressures, respectively, as the mean excess pressures that either depend upon the sound wave only (i. e., with $C = 0$), or on the sound wave together with a constraint which determines the constant C that contributes to the pressure. The concept of the radiation pressure enables the calculation of forces acting upon material surfaces, such as an interface between two fluids or the surface of a particle or a drop in a sound field. Strictly speaking, one should use the acoustic radiation stress tensor Π to calculate such forces. However, in many situations, such as when the surface is rigid or when the velocity at a surface is normal to that surface, it is convenient to use the radiation pressure rather than the full stress.

Sound Radiated by Traveling Flexural Waves

Following Pierce [2] and referring to Fig. 1, consider an infinite plane wall situated at $y = 0$, the region above which (i. e., $y > 0$) is occupied by a fluid with sound speed c_0. Suppose that the wall is undergoing small-amplitude transverse vibrations in the form of a traveling wave that propagates in the positive x-direction, parallel to the wall. In other words, suppose the normal displacement of points on the wall to be of the form $\eta(x, t) = \eta(t - x/c_{\mathrm{W}})$, where c_{W} is the speed of the flexural wave along the wall. The normal velocity of points on the wall is thus given by $v_{\mathrm{W}}(t - x/c_{\mathrm{W}}) = \partial\eta/\partial t$. We consider the limit when $|v_{\mathrm{W}}| \ll c_0$.

The nature of the acoustic disturbance generated in the fluid depends critically upon whether the flexural wave speed is subsonic ($c_{\mathrm{W}} < c_0$) or supersonic ($c_{\mathrm{W}} > c_0$) with respect to the sound speed in the fluid. In the subsonic case, the disturbance in the fluid (generated by constant-frequency excitation of the wall) dies out exponentially with distance y from the surface. On the other hand, when the flexural waves are supersonic relative to the fluid sound speed, plane waves are launched in the fluid at some angle relative with the wall or the vertical. To see this, consider a plane pressure wave in the fluid that propagates in the direction of a unit normal $\hat{\boldsymbol{n}}$. The pressure field for such a wave is taken to be of the form given by Eq. (13), $p_1(\boldsymbol{x}, t) = f(t - \hat{\boldsymbol{n}} \cdot \boldsymbol{x}/c_0)$, satisfying the linear wave equation. The fluid velocity field is therefore given by Eq. (14). Let θ denote the angle between the direction of propagation $\hat{\boldsymbol{n}}$ and the y-axis, as identified in Fig. 1, so that unit vector $\hat{\boldsymbol{n}}$ can be expressed as $\hat{\boldsymbol{n}} = \sin(\theta)\hat{\boldsymbol{i}} + \cos(\theta)\hat{\boldsymbol{j}}$, with $\hat{\boldsymbol{i}}$ and $\hat{\boldsymbol{j}}$ the unit vectors parallel to the x- and y-axes. The y-component of the fluid velocity at the wall is thus given by $\hat{\boldsymbol{j}} \cdot \boldsymbol{v}_1 \Big|_{y=0} = \cos(\theta)(\rho_0 c_0)^{-1} f(t - \sin(\theta)x/c_0)$. This must match the wall velocity that is given by $v_{\mathrm{W}}(t - x/c_{\mathrm{W}})$. One

thus finds the relationships:

$$\sin(\theta) = \frac{c_0}{c_w}\,, \quad f(t) = \frac{\rho_0 c_0}{\cos(\theta)} \boldsymbol{v}_w(t)\,, \tag{20}$$

valid in the supersonic regime $c_w > c_0$. That is, the sine of the propagation angle of the plane waves relative to the vertical direction is given by the ratio of the fluid sound speed to the speed of the flexural waves, and the amplitude and functional form of the pressure of the plane waves in the fluid are determined by the functional form of the transverse velocity of the material points on the wall.

The intensity vector of the radiated plane wave in the fluid, which is a measure of the acoustic energy flux carried by the waves, is given by

$$\boldsymbol{I} = \hat{\boldsymbol{n}} \frac{\rho_0 c_0}{\cos^2(\theta)} \left[\boldsymbol{v}_w(t - \hat{\boldsymbol{n}} \cdot \boldsymbol{x}/c_0)\right]^2 . \tag{21}$$

Note that if c_w decreases toward c_0, θ tends to $\frac{\pi}{2}$ and the direction of propagation becomes parallel to the wall. In that limit, $\cos(\theta) \to 0$ and the radiated acoustic power tends to infinity. This limit cannot be realized because generation of such acoustic waves in the fluid will rapidly deplete the vibrational energy of any such flexural waves [2].

Key Research Findings

We now apply the fundamental concepts outlined above to three specific examples that are relevant to the topic of droplet transport by acoustics; namely, acoustic droplet ejection, droplet transport along a solid surface using surface acoustic waves, and acoustic levitation of droplets.

Acoustic Droplet Ejection

When a focused acoustic beam is directed toward a liquid–air interface from the liquid side, it can cause the ejection of discrete droplets of the liquid that can then be captured by or deposited onto other surfaces. This is shown schematically in Fig. 2. This acoustic droplet ejection (ADE) method and multiple patents based thereupon are the technological basis for the company Labcyte Inc. (Sunnyvale, CA) which uses it for dispensing and liquid handling directed at high-throughput applications [4]. A variety of liquid solvents, containing DNA, proteins, or live cells can be dispensed without loss of activity, at varying volumes ranging from picoliters to microliters.

To model this process, it is instructive to consider first the reflection of a plane wave from a fluid-fluid interface at normal incidence. To this end, we follow a procedure similar to Lighthill [3] who treats the general problem of transmission of waves through junctions. Suppose the interface between the fluids is located at $x = 0$, with the fluid on the left having properties ρ_0 and c_0, while the one on the right has properties $\hat{\rho}_0$ and $\hat{c}_0$. We will affix a caret to quantities that pertain to the fluid on the right. Consider an incident (i. e., right-going) pressure wave in the left fluid given by $p_{1i} = f(t - x/c_0)$. The reflected wave will be a left-going wave of the form $p_{1r} = g(t + x/c_0)$, with the total pressure wave in fluid 1 being the sum of the incident and reflected waves: $p_1 = f(t - x/c_0) + g(t + x/c_0)$. The transmitted wave in the right fluid will be a right-going wave given by $\hat{p}_1 = h(t - x/\hat{c}_0)$. Using the plane-wave relations, the x-velocities in the two fluids are then given by $v_1 = (\rho_0 c_0)^{-1}[f(t - x/c_0) - g(t + x/c_0)]$ and $\hat{v}_1 = (\hat{\rho}_0 \hat{c}_0)^{-1} h(t - x/\hat{c}_0)$. On equating the pressure and velocities at the interface $x = 0$ we find:

$$f(t) + g(t) = h(t) \tag{22}$$

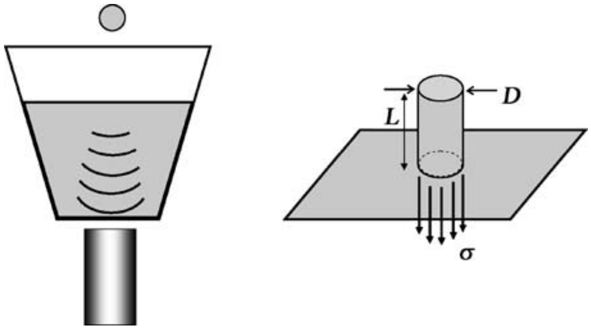
$$(\rho_0 c_0)^{-1}[f(t) - g(t)] = (\hat{\rho}_0 \hat{c}_0)^{-1} h(t)\,. \tag{23}$$

Equations (22) and (23) can be solved for the waveforms of the reflected and transmitted waves, $g(t)$ and $h(t)$, in terms of the waveform of the incident wave $f(t)$ and the ratio $Z = \hat{\rho}_0 \hat{c}_0 / \rho_0 c_0$ of the impedances of the two fluids. The result is that:

$$g(t) = \frac{Z - 1}{Z + 1} f(t)\,, \quad h(t) = \frac{2Z}{Z + 1} f(t)\,. \tag{24}$$

Lighthill [3] points out that for plane wave transmission in channels and tubes, one should actually account for the cross-sectional area change at junctions as well. That is, rather than equating the velocities of the two fluids at junctions, the volumetric flow rates should be equated. For infinite plane waves, our treatment is accurate. If the two fluids have equal impedances so that $Z = 1$, there is no reflected wave ($g(t) = 0$) and the transmitted wave is identical to the incident wave ($h(t) = f(t)$). On the other hand, if the impedance in the right fluid is much less than that

T



Transport of Droplets by Acoustics, Figure 2 Acoustic droplet ejection

of the left fluid, so that $Z \approx 0$, there will be no transmitted wave ($h(t) \approx 0$) and the reflected waveform is given by $g(t) \approx -f(t)$. This corresponds to the case of waves in water reflecting from a water–air interface, since air has a much lower density and sound-speed (and therefore impedance) than water. Such an interface is often referred to as a pressure–release surface [2] since the pressure at such a perfectly-reflecting interface turns out to be zero.

Now suppose that the incident wave is actually of the form

$$p_{1i} = \mathrm{Re}\left\{A\, e^{i(kx-\omega t)}\right\} , \tag{25}$$

corresponding to a sinusoidal wave of radian frequency ω and wavenumber k (or wavelength $\lambda = 2\pi/k$), with complex amplitude A. Note that the wavenumber and frequency are related by $\omega/k = c_0$. Here Re denotes the real part of its complex argument. Upon incidence on a pressure-release surface, the reflected wave is thus given by

$$p_{1r} = -\,\mathrm{Re}\left\{Ae^{i(-kx-\omega t)}\right\} , \tag{26}$$

which, when added to the incident wave, produces a standing wave of the form:

$$p_1 = 2|A| \cos(\omega t) \sin(kx) , \tag{27}$$

to within an arbitrary shift of the time axis. The corresponding density and velocity fields are then given by

$$\rho_1 = \frac{2|A|}{c_0^2} \cos(\omega t) \sin(kx) , \tag{28}$$

$$\boldsymbol{v}_1 = \frac{-2|A|}{\rho_0 c_0} \sin(\omega t) \cos(kx)\hat{\boldsymbol{i}} , \tag{29}$$

and the time-averaged acoustic energy density turns out to be

$$\langle w \rangle = \frac{|A|^2}{\rho_0 c_0^2} . \tag{30}$$

The Langevin radiation pressure on the interface, given by Eq. (19) with $C = 0$, is therefore also given by

$$\left\langle p^{\mathrm{L}} - p_0 \right\rangle = \frac{|A|^2}{\rho_0 c_0^2} . \tag{31}$$

Wang and Lee [1] provide the corresponding results for a plane wave incident on an interface separating fluids whose impedance ratio is Z, as defined above. The difference in the Lagrangian mean excess pressure across the interface is then

$$\left\langle p^{\mathrm{L}} - \hat{p}^{\mathrm{L}} \right\rangle = \frac{|A|^2}{\rho_0 c_0^2} \frac{(1 + Z^2 - 2nZ)}{(1 + Z)^2} . \tag{32}$$

Here $n = c_0/\hat{c}_0$ is the ratio of the wave speeds in the two media. They also provide more general expressions for the case of sound *beams* (rather than plane waves) that are approximated by a one-term Fourier–Bessel series, having both a radial and an axial wave number. The radiation pressure difference (32) at the interface is said to explain the *acoustic fountain* effect where the directed sound beam creates a liquid jet.

Starting with the radiation pressure of a focused acoustic beam at an interface, Elrod et al. [5] have used useful scaling arguments to characterize the acoustic droplet ejection process as a function of pulse energy and frequency. Their model of the ejection considers an initial expulsion of a roughly cylindrical volume of fluid (as depicted on the right side of Fig. 2) due to the impulse (or momentum) imparted to the interface by the focused acoustic beam. The beam is assumed to be on for a time T which is long compared to the period of the wave, $1/f$, but short compared to the time-scale for the dynamics of the liquid. Focused beams are characterized by the diameter D of the focal spot and axial length L which measures the depth of focus. For an acoustic lens with an F-number of roughly unity, both D and L scale with the wavelength $\lambda = c_0/f$ of the sound wave. Not surprisingly, the diameter of the drop that is finally ejected also scales linearly with the wavelength λ or the reciprocal of the frequency: $D \propto c_0/f$. These same length scales D and L are used to estimate the volume of the cylinder of fluid that is expelled. The volume therefore scales with the cube of the wavelength, or $(c_0/f)^3$. The impulse M delivered to that volume is proportional to the product of the radiation pressure, given by Eq. (31), with the cross-sectional area of the beam, and the time-duration of the pulse, T:

$$M \propto \frac{|A|^2 T\lambda^2}{\rho_0 c_0^2} = \langle w \rangle\, T\lambda^2 = \frac{\left\langle \hat{\boldsymbol{n}} \cdot \boldsymbol{I} \right\rangle T\lambda^2}{c_0} \propto \frac{E}{c_0} . \tag{33}$$

Here, as in [5], we have identified the incident energy pulse E as the product of the acoustic intensity (see Eq. (15)) with the pulse duration and cross-sectional area. This represents the total energy delivered by the beam while it is on. Equating the impulse to the initial momentum of the ejected cylinder, one finds the scaling for the

initial velocity

$$U_{\text{init}} \propto \frac{M}{\rho_0 \lambda^3} \propto \frac{Ef^3}{\rho_0 c_0^4} . \tag{34}$$

The initial velocity of the jet appears to scale linearly with the total pulse energy and with the third power of the acoustic frequency.

As the liquid column is ejected with the above initial velocity due to the impulse delivered by the sound beam, it is continually acted upon by the surface tension σ of the liquid which pulls it downward toward the main liquid bath with a force given by the product of σ with the circumference of the circular cross section of the cylinder $\pi D \propto \lambda$ (see Fig. 2). This constant force decelerates the column until it comes to rest at time

$$t_{\text{rise}} \propto \frac{Ef}{c_0^2 \sigma} , \tag{35}$$

having reached the height

$$h_{\text{rise}} \propto \frac{E^2 f^4}{\rho_0 c_0^6 \sigma} . \tag{36}$$

Whether or not a drop can pinch off during this time depends upon the time-scale for the growth of Rayleigh-Plateau instability on a liquid column, which is given by

$$t_{\text{RP}} \propto \left(\frac{\rho_0 \lambda^3}{\sigma} \right)^{\frac{1}{2}} = \left(\frac{\rho_0 c_0^3}{\sigma f^3} \right)^{\frac{1}{2}} , \tag{37}$$

exhibiting a frequency dependence of $f^{-3/2}$. If the pinch-off time is less than the rise time, a drop can be ejected from the column due to the development of the Rayleigh instability before it returns to the main liquid bath below by the pulling action of surface tension.

Elrod et al. [5] have provided most of the above scaling laws, but have not made use of the fact that a threshold energy for droplet ejection can be obtained by requiring that

$$t_{\text{RP}} < t_{\text{rise}} , \tag{38}$$

so that the drop pinch-off due to Rayleigh-Plateau instability can occur prior to the column returning to the bath. The threshold energy is thus found to be:

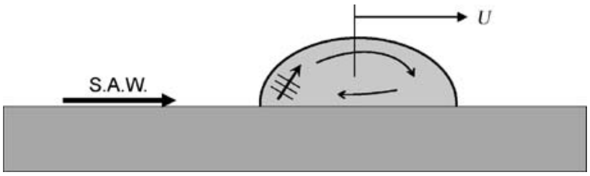
$$E > \frac{\rho_0^{\frac{1}{2}} c_0^{\frac{7}{2}} \sigma^{\frac{1}{2}}}{f^{\frac{5}{2}}} . \tag{39}$$

The $f^{-5/2}$ frequency dependence is consistent with experimental observations reported in [5] for which a least-squares fit provides a dependence of the form $f^{-2.3\pm0.2}$. Typical magnitudes for water droplet ejection using a 5 MHz focused beam include a drop of approximately one wavelength in diameter ($\lambda \approx 300\,\mu$m) and a threshold energy in the range of tens of microjoules [5]. Interestingly, most of the energy in the wave is reflected as the interfacial and kinetic energies of the resulting drop are in the nanojoule range [5]. The characteristic time (37) for the Rayleigh instability to lead to droplet pinch-off is hundreds of microseconds, whereas the acoustic pulse used to generated the droplet lasts approximately 20 microseconds, in accordance with the view that the effect of the acoustic beam can be modeled as delivering an initial impulse to the liquid.

A more recent study of droplet ejection from small micromachined nozzles is provided in [6]. The acoustic droplet ejection method has found applications in photoresist deposition and matrix-assisted laser desorption ionization (MALDI) analysis [4], among others.

Droplet Transport by Surface Acoustic Waves

A recent application of acoustics to droplet transport has been through the use of surface acoustic waves (SAW) to move sessile droplets attached to a solid surface [7–9]. The physical basis for this process has been described in simple terms as follows. When a SAW propagating along a surface encounters a liquid drop, as depicted in Fig. 3, by the mechanism described earlier where flexural waves on a solid launch acoustic waves in the surrounding fluid, they launch plane waves at an angle given by Eq. (20) on the side of the liquid drop that they first encounter. The SAW and the corresponding acoustic waves that they generate in the drop diminish rapidly as one moves away from the leading edge of the drop. The acoustic field thus generated within the drop produces a radiation pressure distribution on the drop interface that tends to deform the drop and modify the contact angles at the leading and trailing edges of the drop. Also, mediated by an effect known as acoustic streaming, an internal flow field is generated within the



Transport of Droplets by Acoustics, Figure 3 Droplet transport by surface acoustic waves

T

drop that leads to its translational motion parallel to the direction of the original SAW. Typical droplet volumes that are actuated by this effect are tens of nanoliters, although smaller volumes (tens of picoliters) can be left behind on appropriately patterned surfaces as the larger drops move along.

In references [7–9] that describe this phenomenon, the SAW is generated on a piezoelectric substrate with interdigital gold transducers. Typical values of the SAW frequencies and wavelengths are in 100 s of MHz and 10 s of μm, respectively, with the surface wave velocity c_{w} in the range 3000 – 4000 m/s. The amplitude of the waves is said to be in the nanometer range. An order of magnitude analysis can be used to estimate characteristic values of the wave amplitudes that can be established in the droplet. Using an SAW velocity of $c_{\mathrm{w}} = 3000\,\mathrm{m/s}$ and frequency of $f = 100\,\mathrm{MHz}$ provides an SAW wavelength of 30 microns. If we take the amplitude of the wave to be $\varepsilon = 1$ nanometer, the amplitude of the plane pressure waves that get launched in the liquid is estimated to be

$$\frac{2\pi f \varepsilon \rho_0 c_0}{\sqrt{1-(c_0/c_{\mathrm{w}})^2}} \approx 10^6\,\mathrm{Pa}$$

or about 10 atmospheres. The energy density w of such waves (cf. Eqs. (12) and (15)) is approximately $500\,\mathrm{J/m^3}$ or 500 Pa, however. Based on Eq. (19), this is also the approximate magnitude of the radiation pressure that would act upon the droplet interface.

Although a detailed analysis of the flow field within the sessile drops has not been carried out, the coupling between the SAW and the liquid via the oblique plane waves that are launched in the liquid is thought to give rise to acoustic streaming within the droplets or other bulk liquids that are in contact with the solid surface [7–9]. Acoustic streaming refers to nonzero time-averaged bulk flows that result in fluids under the influence of primarily time-periodic acoustic waves [10]. Since time-periodic quantities arising form linear acoustic disturbances have a zero mean, acoustic streaming, like the radiation pressure effect, is based upon nonzero averages of quadratically nonlinear terms. One also needs to include viscous effects in the description. Thus, the divergence of the viscous stress, $\nabla \cdot \tau$, is first added to the right-hand side of the conservation of momentum equation (2). Here, $\tau = \mu[\frac{1}{2}(\nabla \boldsymbol{v} + \nabla \boldsymbol{v}^{\dagger}) - \frac{1}{3}\boldsymbol{\delta}(\nabla \cdot \boldsymbol{v})] + \kappa \boldsymbol{\delta}(\nabla \cdot \boldsymbol{v})$, with μ the shear viscosity of the fluid and κ its dilatational or bulk viscosity. Upon time-averaging the resulting momentum equation and ignoring the dilatational terms that contain $\nabla \cdot \boldsymbol{v}$, one obtains the analog of Stokes equations for the time-averaged quantities, but with an effective body force term, in the form [10]:

$$\nabla \langle p \rangle - \mu \nabla^2 \langle \boldsymbol{v} \rangle = F_e \,. \tag{40}$$

Since acoustic fields p_1 and $\boldsymbol{v}_1$ generally have zero time-averages, the averaged quantities appearing in Eq. (40) could be regarded as being the averages of p_2 and $\boldsymbol{v}_2$ in the series expansions (5) and (6). The effective force, however, involves averages of quadratically nonlinear terms in the first-order quantities, namely

$$F_e = -\nabla \cdot \langle \rho \boldsymbol{v} \boldsymbol{v} \rangle \approx -\nabla \cdot \langle \rho_0 \boldsymbol{v}_1 \boldsymbol{v}_1 \rangle \,. \tag{41}$$

Thus, to analyze acoustic streaming, one must first solve the equations of linear acoustics to obtain the first-order fields. This is followed by the calculation of the effective body force (41) and the solution of the Stokes equation (40) for the time-averaged streaming flow, driven by the effective force. Guttenberg et al. [7] have carried out such an analysis to investigate pumping in a capillary gap driven by SAW.

Acoustic Levitation

In a standing pressure wave characterized by time-periodic acoustic pressure and velocity fields $p_1(\boldsymbol{x}, t)$ and $\boldsymbol{v}_1(\boldsymbol{x}, t)$, consider a spherical droplet of radius R (small compared to the acoustic wavelength) to be located at a given position in space. Upon calculating the scattered acoustic field in the vicinity of the droplet and the resulting radiation pressure acting on its interface, a net force is found to be acting on the drop, obtained via integration of the product of the radiation pressure and the inward-pointing unit normal vector on the entire drop surface. A convenient way to express this acoustic levitation force, F, is in terms of the negative gradient of a potential energy function U, i. e., $F = -\nabla U$, with the potential energy field given by

$$U = 2\pi R^3 \left[\frac{g_1}{3\rho_0 c_0^2} \left\langle p_1^2 \right\rangle - \frac{g_2 \rho_0}{2} \langle \boldsymbol{v}_1 \cdot \boldsymbol{v}_1 \rangle \right] . \tag{42}$$

This result, which is due to Gor'kov (1962), is reviewed in [1] and [11]. The angular brackets denote the time-averages of their arguments at a fixed position in space and dimensionless functions g_1 and g_2 are related to the ratios of the properties of the droplet phase and those of the external fluid. In particular, with $\Lambda = \hat{\rho}_0/\rho_0$ and $\Sigma = \hat{c}_0/c_0$ respectively representing the density ratio and sound speed ratio of the droplet phase (identified with a caret) to the external fluid, these functions are given by

$$g_1 = 1 - \frac{1}{\Lambda \Sigma^2} \tag{43}$$

$$g_2 = \frac{2(\Lambda - 1)}{2\Lambda + 1} . \tag{44}$$

For instance, if in the absence of the droplet, there exists a standing pressure wave of the form: $p_1 = A\sin(kz)\cos(\omega t)$, for which a pressure node is located at $z = 0$, when the droplet center is located at $z = Z$, it experiences the force:

$$F_z(Z) = -\frac{\pi A^2 k R^3}{\rho_0 c_0^2}\left[\frac{g_1}{3} + \frac{g_2}{2}\right]\sin(2kZ) . \tag{45}$$

This force can drive the droplet toward the nodes or the antinodes of the standing wave, depending upon the sign of the factor $g_1/3 + g_2/2$ which in turn depends on the properties of the two fluids. When that factor is positive, the droplets move toward the nodes.

As an application of this effect, a number of recent papers [12–14] have demonstrated and analyzed the potential for concentrating aerosol droplets in cylindrical cavities and for sheathless focusing of particles in a flow cell for subsequent interrogation and sorting. The concentrators are constructed from piezoelectric materials or consist of flow cells that are gel-coupled to piezoelectric transducers and driven at or near resonance modes. Slight modifications to the cavity geometry have been found to have significant impact on the precise positioning of the particles or droplets. The modeling efforts in this area generally require determination of the radiation potential U for the given channel/cavity geometry and investigating the effects of symmetry-breaking changes to the geometry on the radiation potential in order to predict the degree of localization of the particles. The application to sheathless focusing [13] is particularly promising for the development of Lab-on-Chip flow cytometry systems.

Future Directions for Research

There are a number of open problems that can be treated using the modeling principles that have been summarized above. For instance, in the problem of transport of sessile droplets by surface acoustic waves, a detailed understanding of the internal flow within the droplet has not yet emerged. Nor are there simple scaling laws that design engineers can use to predict the speed of droplet motion as a function of the surface wave characteristics and droplet size and physical properties. In acoustic droplet ejection, one can anticipate more detailed computational studies of the droplet pinch-off process using boundary integral methods, initiated in [5], and more sophisticated numerical techniques for multiphase flow systems with interfaces, e. g., the level-set method [15]. The same techniques can also be applied to the problem of acoustic levitation of droplets in order to gain a better understanding of the deformed shapes of levitated droplets [16] or their shape mode oscillations.

Thermocapillary actuation

Definition

Transport of droplets by thermal capillarity is an actuation concept utilizing thermocapillary forces. A temperature gradient across a liquid droplet leads to a difference in surface tensions at both ends of the droplet. The surface tension difference drives the liquid droplet toward the cooler place.

Overview

Droplet-based microfluidics promises a number of applications for chemical analysis and synthesis. Generally, droplet transport can be achieved by manipulating a droplet's surface tension. Electrowetting or electrocapillarity is a common method for transport, where electrostatic force changes the contact angles and propels a droplet. Thermocapillarity utilizes the temperature dependency of interfacial tension for transporting a droplet. Temperature field on a solid substrate generated by heaters leads to a temperature gradient across a droplet and consequently a surface tension difference across the two ends of the droplet. The imbalance of surface tension makes the droplet move toward a cooler place. Transport of droplets by thermal capillarity is a coupled problem between heat transfer in a solid substrate and the surface tension-driven motion based on Newton's second law.

Basic Methodology

Transport of a Liquid Droplet in a Transient Temperature Field

Figure 1 shows a basic model of the motion of a liquid droplet inside a capillary and under a transient temperature field. At a relatively low heater temperature, the heat radiation can be neglected. The energy equation for heat transport in the capillary wall can be formulated with heat conduction and free convection as

$$\frac{\mathrm{d}T}{\mathrm{d}t} = \alpha \frac{\mathrm{d}^2 T}{\mathrm{d}x^2} - \frac{2hR_\mathrm{o}}{\rho c \left(R_\mathrm{o}^2 - R_\mathrm{i}^2\right)} T \tag{1}$$

where T is the temperature difference between the capillary temperature and the ambient temperature, and α, ρ and c are the thermal diffusivity, the density and the specific heat capacity of the capillary material. R_o and R_i are the outer and inner radii of the capillary as depicted in Fig. 1. The transient boundary conditions of the temperature field are

$$t = 0: \quad T(x) = 0$$

$$t > 0: \quad \begin{cases} x = 0\,, & \left.\dfrac{\mathrm{d}T}{\mathrm{d}x}\right|_{x=0} = -\dfrac{q''}{k} \\ x = L_\mathrm{c}\,, & T = 0 \end{cases}$$

where L_c, q'', k, R_o and R_i are the length of the capillary, the heat flux, the heat conductivity of the capillary's material and the outer and the inner radii of the capillary, respectively. Using the dimensionless variables

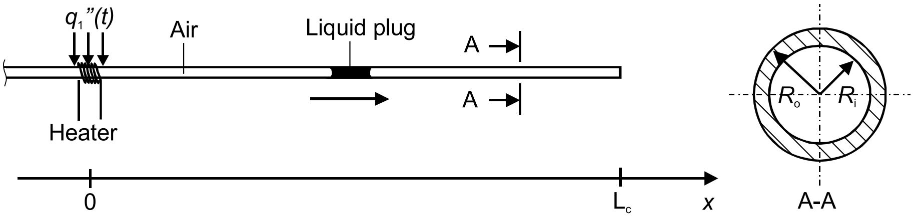
$$T^* = \frac{T}{q'' L_\mathrm{c} k}\,, \quad x^* = \frac{x}{L_\mathrm{c}}\,, \quad t^* = \frac{t}{L_\mathrm{c}^2 \alpha}$$

and the dimensionless parameter

$$\beta = \sqrt{\frac{2hR_o L_\mathrm{c}^2}{k\left(R_\mathrm{o}^2 - R_\mathrm{i}^2\right)}}$$

leads to the dimensionless form of Eq. (1):

$$\frac{\partial T^*}{\partial t^*} = \frac{\partial^2 T^*}{\partial x^{*2}} - \beta T^* \tag{2}$$



Transport of Droplets by Thermal Capillarity, Figure 1 Model of thermocapillary effect of a liquid droplet in a transient temperature field

as well as the dimensionless boundary conditions:

$$t^* = 0: \quad T^*\left(x^*\right) = 0$$

$$t^* > 0: \quad \begin{cases} x^* = 0, & \dfrac{\partial T^*}{\partial x^*} = -1 \\ x^* = 1, & T^* = 0 \end{cases}$$

Using separation of variables and Fourier series transformation, the solution of the partial differential Eq. (2) is

$$T^* = \frac{1}{\beta}\left[\frac{\sinh(\beta)}{\cosh(\beta)}\cosh\left(\beta x^*\right) - \sinh\left(\beta x^*\right)\right] + \sum_{n=1}^{\infty} D_n \exp\left\{-\left[\left(n-\tfrac{1}{2}\right)^2\pi^2 + \beta^2\right]t^*\right\} \times \cos\left[\left(n-\tfrac{1}{2}\right)\pi x^*\right]$$

$$\frac{\partial T^*}{\partial x^*} = \left[\frac{\sinh(\beta)}{\cosh(\beta)}\sinh\left(\beta x^*\right) - \cosh\left(\beta x^*\right)\right] - \sum_{n=1}^{\infty}\left(n-\tfrac{1}{2}\right)D_n \times \exp\left\{-\left[\left(n-\tfrac{1}{2}\right)^2\pi^2 + \beta^2\right]t^*\right\} \times \sin\left[(n-\frac{1}{2})\pi x^*\right]$$

$$D_n = 2\int_0^1 \left\{-\frac{1}{\beta}\left[\frac{\sinh(\beta)}{\cosh(\beta)}\cosh\left(\beta x^*\right) - \sinh\left(\beta x^*\right)\right]\right\} \times \cos\left[\left(n-\frac{1}{2}\right)\pi x^*\right] \mathrm{d}x^* \tag{3}$$

Figure 2 depicts the analytical transient behavior of the dimensionless temperature distribution along the capillary. The circles represent the position of the droplet in this space–time coordinate system. The liquid droplet is predicted to accelerate first and then slow down when it moves out of the temperature field.

The surface tension is a function of the temperature, which in turn is a function of the position x if a weak thermal interaction between the droplet and the capillary can be assumed:

$$\sigma_{\mathrm{lg}}(T) = f\left[T(x)\right] = g(x) = \sigma_{\mathrm{lg}}(x) \tag{4}$$

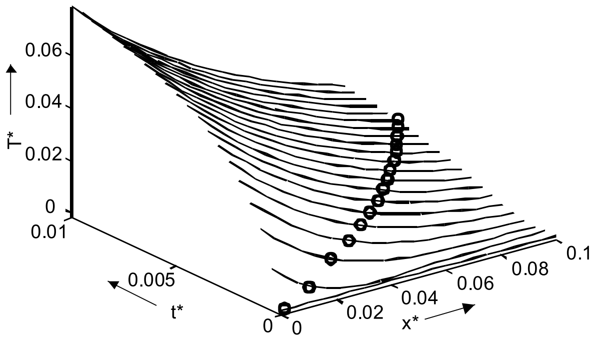
The simplest model for the friction between the liquid droplet and the capillary wall is the Hagen–Poiseuille model:

$$\frac{\mathrm{d}p}{\mathrm{d}x} = \frac{8\mu}{R^2}\frac{\mathrm{d}x}{\mathrm{d}t}$$

where $R = R_\mathrm{i}$ is the radius of the droplet and μ is the dynamic viscosity of the liquid. The governing equation for the movement of the liquid drop is

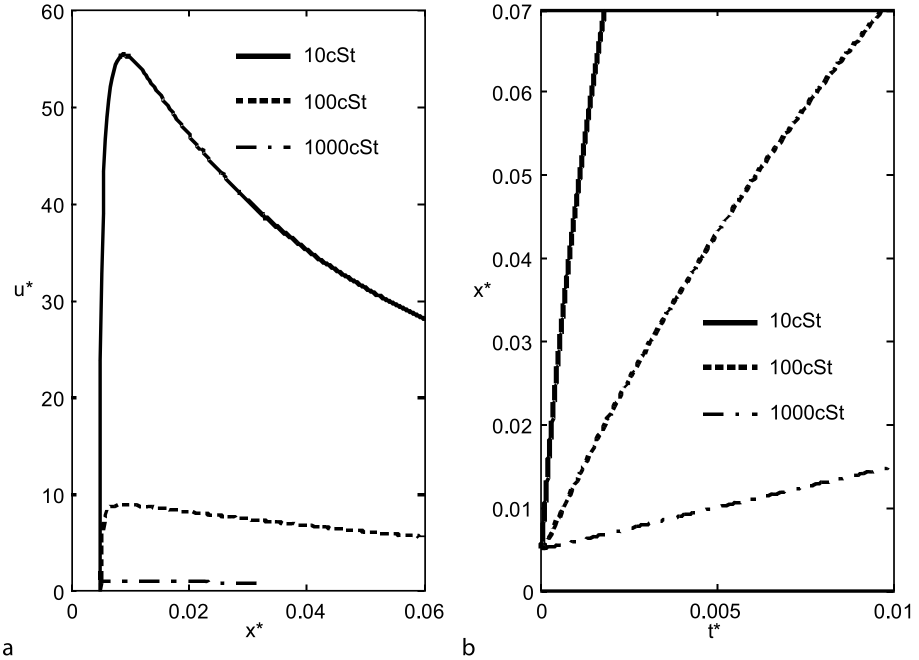
$$\rho\pi R_\mathrm{o}^2 L\frac{\mathrm{d}u}{\mathrm{d}t} = -8\pi\mu L u + 2\pi R_\mathrm{o}\left[\sigma_{\mathrm{lg}}(x)\cos\theta_\mathrm{r} - \sigma_{\mathrm{lg}}(x+L)\cos\theta_\mathrm{a}\right] = 0 \tag{5}$$

where L, θ_r and θ_a are the length and the contact angles at the receding and advancing ends of the liquid droplet,



Transport of Droplets by Thermal Capillarity, Figure 2 Graphical representation of the dimensionless transient temperature distribution along the capillary. The circles are the corresponding droplet position in this field

T



Transport of Droplets by Thermal Capillarity, Figure 3 Position and velocity of the droplet versus time

respectively. Introducing the velocity $u = \mathrm{d}x/\mathrm{d}t$, rearranging Eq. (5) and introducing the kinetic viscosity $\nu = \mu/\rho$, the governing equation of the droplet's motion is

$$\frac{\mathrm{d}u}{\mathrm{d}t} + \frac{8\nu}{R^2}u + \frac{2}{\rho RL}\left[\sigma_{\mathrm{lg}}(x+L)\cos\theta_{\mathrm{a}} - \sigma_{\mathrm{lg}}(x)\cos\theta_{\mathrm{r}}\right] = 0 \tag{6}$$

For a small temperature range, the surface tension can be assumed as a linear function of the temperature:

$$\sigma_{\mathrm{lg}}(T) = \sigma_{\mathrm{lg}0} - \gamma\,(T - T_0)$$

Finally, the velocity of the droplet is determined as

$$u = \frac{B}{A}\left[1 - \exp(-At)\right] \tag{7}$$

with

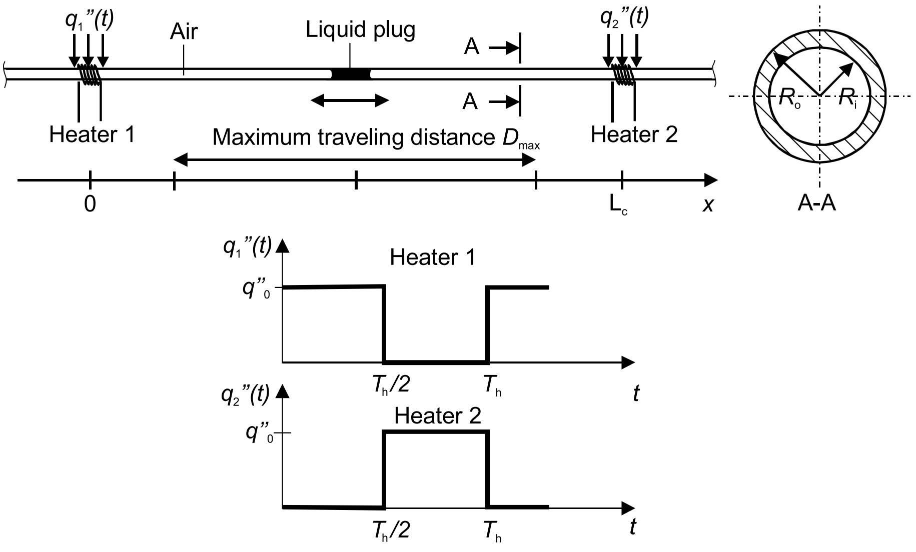
$$A = \frac{8\nu}{R_{\mathrm{o}}^2}$$

$$B = \frac{2}{\rho R^0 L}\left[\sigma_{\mathrm{lg}}(x+L)\cos\theta_{\mathrm{a}} - \sigma_{\mathrm{lg}}(x)\cos\theta_{\mathrm{r}}\right]$$

Because $L \ll L_{\mathrm{c}}$, the same contact angles at the two ends of the droplet can be assumed. Normalizing the spatial variable, the time and the velocity by L_{c}, L_{c}^2/α and α/L_{c}, respectively, results in the dimensionless velocity:

$$\begin{aligned} u^* &= \frac{B^*}{A^*}\left[1 - e^{-A^* t^*}\right] \\ A^* &= \frac{8\nu}{R_{\mathrm{o}}^{*2}\alpha} \\ B^* &= \frac{2L^3 q''}{\rho R_{\mathrm{o}}^* k\alpha^2}\gamma\cos(\theta)\frac{\mathrm{d}T^*}{\mathrm{d}x^*} \end{aligned} \tag{8}$$

where the asterisk denotes the dimensionless variables. Note that the above dimensionless velocity is the ratio between the droplet velocity and the characteristic spreading velocity of heat in the capillary. Figure 3 shows the position and velocity of the droplet versus time with different liquid viscosities. From the analytical results, it is clear that liquids with lower viscosities can travel much further than those with higher viscosities. As expected from the results of the temperature field, the liquid droplet first accelerates, and then slows down. The acceleration period is determined by A^* in Eq. (8) or the ratio between the kinematic viscosity (momentum diffusivity) of the liquid and the thermal diffusivity of the capillary material. The stabilizing period is determined by B^* or the heat transfer in the capillary wall as modeled in Eq. (8). The less viscous droplet will initially accelerate faster and reach a higher velocity. The velocity then decreases until



Transport of Droplets by Thermal Capillarity, Figure 4 Model of thermocapillary effect of a liquid droplet in a periodic temperature field

the droplet stops when it moves out of the temperature field. A smaller dimensionless capillary radius R_o^* leads to a higher value of B^* , and consequently to a higher velocity.

Transport of a Liquid Droplet in a Periodic Temperature Field

Figure 4 shows a model of a liquid droplet inside a capillary and under a periodic temperature field. At a relatively low heater temperature, heat radiation can be neglected. The energy equation for heat transport in the capillary wall formulated with heat conduction and free convection remains the same as in the case of a transient temperature field (Eq. (1)), but the periodic boundary conditions are now

$$\left.\frac{\mathrm{d}T}{\mathrm{d}x}\right|_{x=0} = -\frac{q_1''}{k} = -\frac{q''}{k} f_1(t)$$

$$\left.\frac{\mathrm{d}T}{\mathrm{d}x}\right|_{x=L} = -\frac{q_2''}{k} = -\frac{q''}{k} f_2(t)$$

The functions f_1 and f_2 are depicted in Fig. 4. We can also introduce the dimensionless variables

$$T^* = T\frac{k}{q''L_c}, \quad t^* = \frac{t}{T_h}, \quad x^* = \frac{x}{L_c}$$

Eq. (1) then has the dimensionless form

$$\eta \frac{\mathrm{d}T^*}{\mathrm{d}t^*} = \frac{\mathrm{d}^2 T^*}{\mathrm{d}x^{*}2} - \beta^2 T^* \qquad (9)$$

with

$$\eta = \frac{L_c^2}{\alpha T_h}$$

$$\beta = \sqrt{\frac{2hL_c^2 R_o}{\alpha\rho c\left(R_o^2 - R_i^2\right)}}$$

and the dimensionless boundary conditions

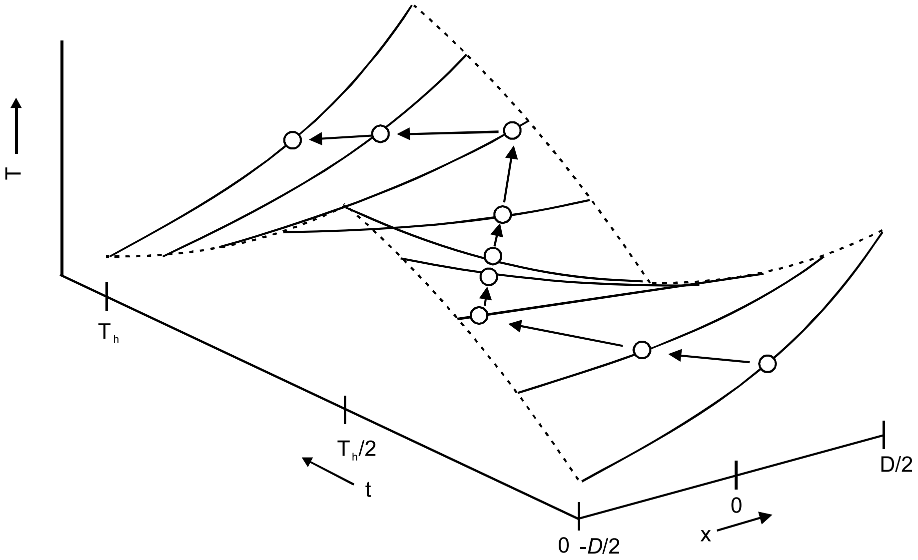
$$\left.\frac{\mathrm{d}T^*}{\mathrm{d}x^*}\right|_{x^*=0} = -f_1\left(t^*\right)$$

$$\left.\frac{\mathrm{d}T^*}{\mathrm{d}x^*}\right|_{x^*=1} = f_2\left(t^*\right)$$

The dimensionless temperature field can then be determined as

$$T^* = \sum_{n=-\infty}^{\infty} \left\{ \frac{F_{2n}\mathrm{e}^{\lambda_n} - F_{1n}}{\lambda_n\left(\mathrm{e}^{2\lambda_n} - 1\right)} e^{\lambda_n x^*} + \left[\frac{F_{2n}\mathrm{e}^{\lambda_n} - F_{1n}}{\lambda_n\left(\mathrm{e}^{2\lambda_n} - 1\right)} - \frac{F_{1n}}{\lambda_n}\right] e^{-\lambda_n x^*} \right\} e^{\mathrm{i}2\pi n t^*}$$

$$T(x,t) = \frac{q''L_c}{k}\,\mathrm{Re}\left(T^*\right) \qquad (10)$$



Transport of Droplets by Thermal Capillarity, Figure 5 Graphical representation of the dimensionless periodic temperature distribution along the capillary. The circles are the corresponding droplet position in this field

where Re represents the real part of a complex number and

$$n = 0 \quad \begin{cases} F_{10} = \int_0^1 f_1\left(t^*\right)\,\mathrm{d}t^* = -0.5 \\ F_{20} = -F_{10} \end{cases}$$

$$n \neq 0 \quad \begin{cases} F_{1n} = \dfrac{\mathrm{i}}{2\pi n}\left[1-(-1)^n\right] \\ F_{2n} = F_{1n} \end{cases}$$

Figure 5 depicts the three-dimensional dimensionless temperature difference. Because of the relatively large thermal capacitance of the capillary, a longer heating period T_h results in a better temperature gradient. If the period is too short, both heaters will contribute to an almost uniform temperature distribution.

The motion of the liquid droplet under this periodic temperature field can be obtained in the same manner as previously in the transient case. According to the result, the damping force acting on the droplet is proportional to its viscosity. The higher the viscosity, the smaller is the maximum peak-to-peak traveling distance. A low-viscosity droplet responds quickly to the change of the temperature gradient and causes an initial overshoot in velocity. At a higher viscosity, the response is damped and the velocity curve will have a typical exponential form. Figure 6 depicts the typical dynamic behavior of a droplet at different viscosities.

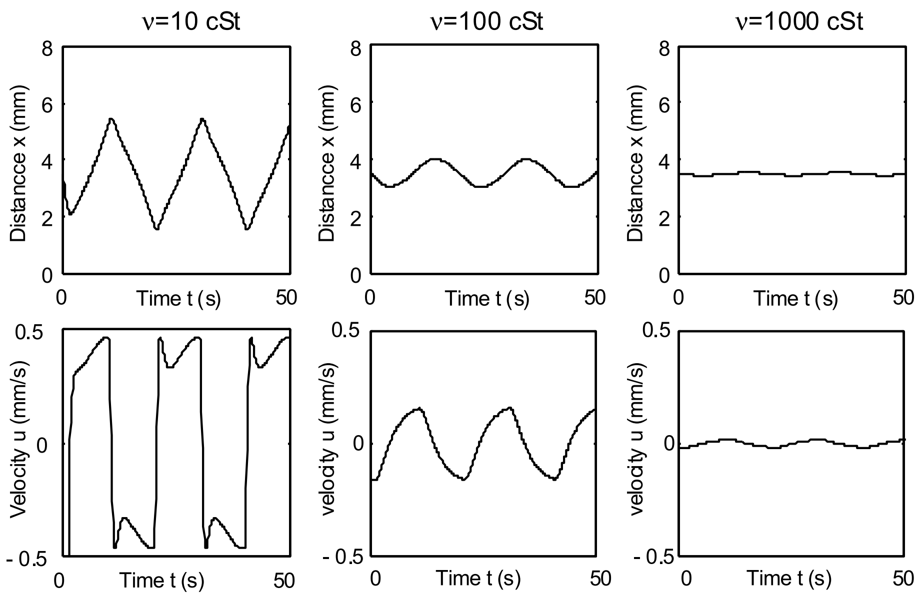
Key Research Findings

Droplet Motion in a Transient Temperature Field

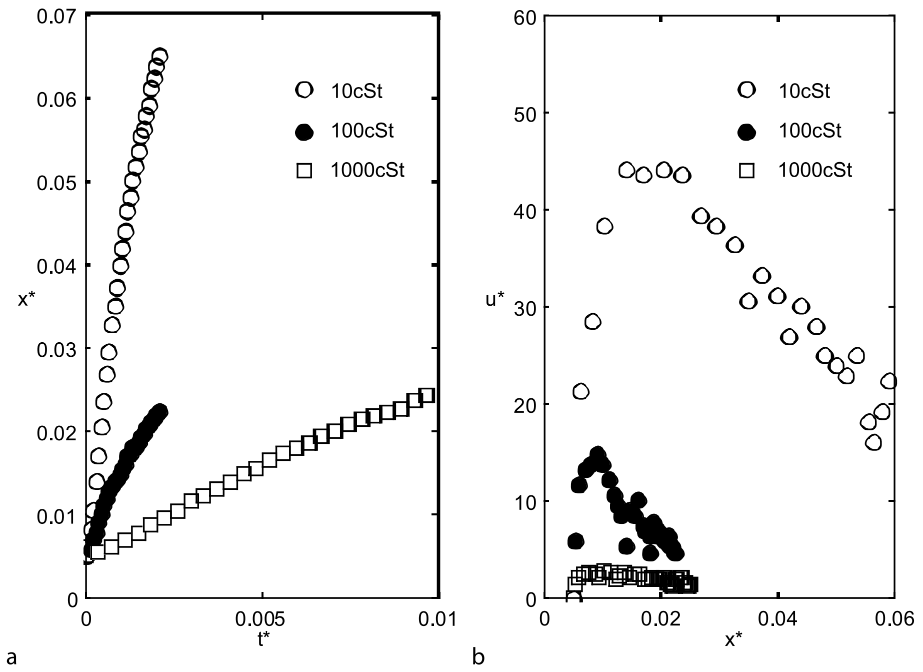
Figure 7 depicts the measurement results of position and velocity of droplets with different viscosities. The experimental results agree relatively well with the theoretical results shown in Fig. 3. The droplet first accelerates in a short time, but most of the distance is traveled in this period. Initially, the temperature at the heater rises quickly, but temperature spreading along the capillary needs more time. Thus, the initial acceleration is controlled by the heat flux, while the later motion depends on the spreading process of the temperature. During this process, the liquid droplet moves to the cooler region because of the initially high velocity. In this region, the temperature gradient decreases significantly leading to a slowing down of the motion.

Periodic Fields

Figure 8 shows the experimental results of the droplet position and velocity in a periodic temperature field at different switching frequencies. In this case, the experimental results agree relatively well with the theoretical prediction in Fig. 6. Based on both experimental and theoretical data, the dynamic behavior of the droplet is determined by a number of parameters such as viscosity, drop length and switching frequency. In general, the droplet motion can follow the temperature change at low switching frequencies. However, the maximum traveling distance decreases at higher frequencies.



Transport of Droplets by Thermal Capillarity, Figure 6 Position and velocity of the droplet versus time at different viscosities

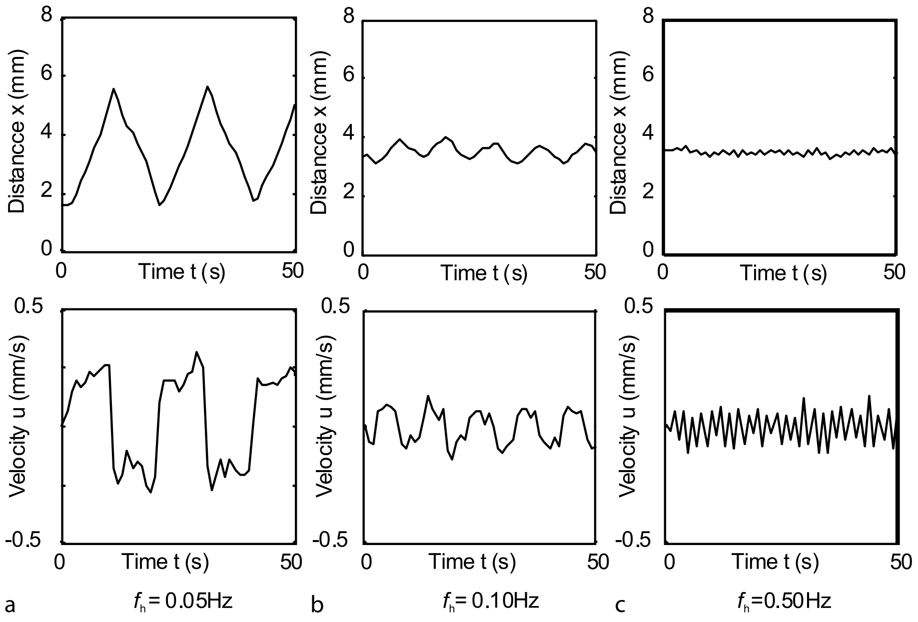


Transport of Droplets by Thermal Capillarity, Figure 7 Measured position versus time and velocity versus position of a droplet in a transient field with different viscosities

A lower liquid viscosity causes a larger traveling distance.

Future Directions for Research

Thermal capillarity is suitable for manipulating liquid droplets in microchannels. Thermocapillary pumps work with the same concept. Theoretical and experimental results show that the droplet motion can be controlled by viscosity, droplet length and the temperature field itself. Using more heaters in an array will allow a more complex droplet motion. In the models presented here the same contact angles at receding and advancing ends were



Transport of Droplets by Thermal Capillarity, Figure 8 Measured position and velocity of the droplet at different switching frequencies

assumed. But this is not the case in reality. The contact angles depend on the temperature and the droplet velocity, which directly affect the motion. Consideration of thermal expansion of the liquid, heat transfer inside the droplet and the capillary wall thickness may lead to further interesting findings.

Traveling-Wave Pump

Definition

A device for fluidic rectification using a series of nozzles located along a channel for issuing short *puffs* of flow which travel through the channel.

In fluidic pumps, the supplied alternating fluid flow is converted into a mostly one-way (and ideally non-return) output flow. One possibility how to do it is generating a series of travelling waves in a channel by alternating outflows and suction in a series of nozzles arranged along a channel. Each travelling wave drags along another fluid which does not necessarily enter the nozzles. In a more sophisticated versions, the outflow from the nozzles utilizes the Coanda effect of flow attachment to a curved wall.

Definition

A flow field is broadly classified as laminar or turbulent. Pressure, velocity and temperature information are used to characterize a flow field. In turbulent flows, these flow variables are random functions of space and time. The coherent and random flow structures/vortices and interactions between them influence the overall behavior of the turbulent flow field. The location of the wall surface, Reynolds number, Mach number, buoyancy force due to temperature and concentration gradients etc. influence the turbulent flow field characteristics. The nature of flow field also depends on the convective or absolute instability mechanism leading to turbulent flow.

The flow control is a mechanism by which the flow field is manipulated to obtain required behavior in comparison to the natural uncontrolled case. The flow control is broadly classified as: (a) passive control, where no auxiliary power source is required and (b) active control, where there is expenditure of energy. In passive control, parameters like geometry, compliance, temperature and porosity etc. are varied. Boundary oscillation, acoustic waves, blowing, suction etc. are used for active control. The active control schemes use actuators for manipulating the flow behavior. The size of these actuators depends on the nature of the flow. When the Reynolds number is increased, the required size of the actuator is reduced. The availability of MEMS fabrication technique has contributed towards small scale actuators development.

Overview

The industrial applications of turbulent flow control, the design requirements of actuators and the various classification schemes of actuators are discussed in the following sections.

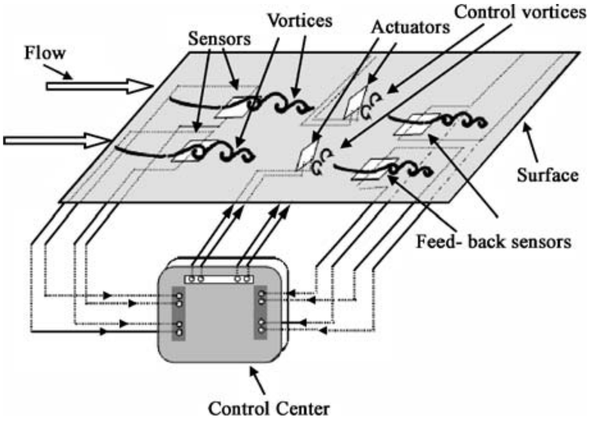
Industrial Applications

The turbulent flow control finds application in various industrial applications: drag reduction, lift enhancement, mixing and or heat transfer enhancement, flow induced noise suppression etc. Reduction in drag of aircraft and underwater body leads to reduced fuel cost and volume. Enhanced heat transfer is desired for heat exchangers and electronic packaging while enhanced mixing is desired in combustors. The reduction in boundary layer noise due to pressure fluctuations helps in operation of under water sonar. To achieve these end results, the flow control techniques aim to control either the transition (delay or advance) or separation (suppression or enhancement) in a wall bounded flow. For an example, when the boundary layer is turbulent on an aircraft wing, the resistance to separation is enhanced and more lift can be attained by operating at higher angle of attack. On the other hand, the skin friction drag for a laminar boundary layer is smaller than that of turbulent boundary layer and therefore the delay in transition leads to lower skin friction drag and flow induced noise.

Implementation Strategy

The turbulent flow control can be implemented through different control schemes [1]. They are: predetermined open-loop control, reactive feed forward open loop control and reactive feedback closed loop control. The physical arrangement of sensors and actuators depend on the nature of control schemes and flow characteristics. The criteria for selection of appropriate actuators have been discussed in next section. It should be noted that the actuators require parasitic power supply for its operation. This fact should be taken into consideration for overall performance analysis of actuators.

Turbulent flow control schemes assume the significant role played by coherent large scale structures or vortices. These structures are responsible for more than 50% turbulence productions. The growth of large coherent structures leads to mixing enhancement. Similarly, the annihilation of large scale structures to small scale structures lead to lower drag. These coherent structures are generated or amplified due to the flow instability and gets convected from the upstream to the downstream locations. The boundary conditions imposed by the actuators located in-between the upstream



Turbulence Control (Microflap, Microballoon, Microsynthetic Jet), Figure 1 A schematic of flow control arrangement

and downstream locations modify the approaching turbulent structures. One possible turbulent flow control implementation scheme is shown in Fig. 1. The physical system on which the flow control scheme is implemented can be subdivided into three subsystems: (a) flow sensors, which characterize the upstream coherent structures, (b) actuators, which modify the wall boundary conditions experienced by the approaching coherent structures and (c) control sensors, which establishes the coherent structures evolution between upstream and downstream locations and the effect of actuations.

The control sensors are used for verification of control objectives. When, the objective is to reduce drag, the control signal is the shear stress. Similarly, for reduction of pressure fluctuations, the control sensors provide the rms value of pressure fluctuations. For implementation of the control scheme, the relationship/transfer function between the upstream sensors and control sensors is established. Similarly, the transfer function between the actuator properties and the control sensors is obtained. These two transfer functions are used to obtain the actuator state for optimal control.

Actuator Requirements

Due to chaotic nature, the turbulent flow is high dimensional in nature. Therefore, the implementation of turbulent flow control schemes for practical applications is challenging. However, the form and structures in a turbulent flow can be diagnosed and control of turbulent flow is realizable by suitable actuation. It is difficult to specify the requirement of an ideal actuator for turbulent flow control. The ideal characteristics of an actuator for turbulent flow control can be described based on the following guidelines.

- Turbulent flow is quite sensitive to the surface roughness. The actuator should not introduce additional roughness to the surface of the device. It should not have parasitic effect on the flow when the actuator is switched off.
- The frequency to be introduced by the actuators should match with the spatial and temporal frequencies present in the turbulent flow. The high Reynolds number flow has spatial and temporal frequency of the order of microns and kHz respectively. Therefore, MEMS based actuators are ideal for turbulent flow control due to their smaller physical dimension and lower inertia.
- Strength is the other requirement of actuator for maintaining the integrity against the load from the fluid forces.
- During implementation of distributed control with multiple actuators for optimal turbulent flow control, the behavior of the actuators should be uniform for all actuators.

The earlier flow control studies using blowing and suction have shown that the velocity due to the movement of the actuator should be of the order of friction velocity u_τ. For blowing based flow control, the flow blows through the boundary layer when the jet velocity is higher and the control is not effective for boundary layer control. The other observation is that when the size of the actuator is higher than the turbulent length scale ($l = \nu/u_\tau$, where ν is the kinematic viscosity and u_τ is the friction velocity), the surface roughness effect becomes predominant. The size of the actuator is usually about ten times the characteristics turbulent length scale. The operating frequency of the actuator is set based on two criteria:

- The actuator frequency is matched with the instability frequency of the flow and this approach is traditionally successful for separation control;
- The actuator frequency is set higher than the unstable frequency of the flow and the frequency content from the actuator is damped.

Here the actuator acts like a constant flux source without any fluctuations content. This mode acts on the main flow and is effective in turbulent boundary layer control for drag reduction.

Actuator Classification

The actuators can be broadly classified based on their principle of operation as: thermal actuators, electro hydrodynamic actuators, magneto hydrodynamic actuators, momentum injection actuators and moving surface actuators.

Thermal actuators are surface mounted electrical resistor, which injects heat into the near wall flow. The heating of

the working fluid influences the instability of the flow in different ways depending on whether the working field is gas or liquid. The injected heat reduces the fluid density when the working fluid is gas leading to generation of buoyant force. When the working fluid is liquid, there is a decrease in fluid viscosity due to increase in temperature influencing the generation of Tollmien–Schlichting waves. The drawback of these actuators is the low frequency response due to the parasitic heat loss to the solid on which it is mounted and high power consumption.

For an electrically conducting fluid (water or ionized gas), the electrical field can induce motions due to the movement of charged ions or the body forces can be generated due to the interactions between magnetic and electric fields. These options are used in electro hydrodynamic and magneto hydrodynamic actuators. The drawbacks of these actuators are the high voltage requirement and significant loss due to the thermal effect. The micro-fabrication procedure of these types of actuators is not yet established.

The momentum injection actuators act like a source of momentum to the flow. One popular approach in this category is blowing. The other popular actuator in this category which does not require any fluid supply is the synthetic jet. The moving surface actuators provide motion of the wall beneath the flow. These actuators inject momentum to the flow by modification of the surface boundary condition. They introduce localized boundary layer disturbances. Flap actuator and balloon actuator belong to the moving surface actuators. The fabrication procedure of microsynthetic jet, microballoon and microflap actuators is established in literature. The practical applications of these actuators have been demonstrated. The present study discusses the details of these three actuators i. e. microsynthetic jet, microballoon and microflap. Other special MEMS based actuators are electrokinetic actuator, microbubble actuator, microvalve actuator and micropolymer actuator.

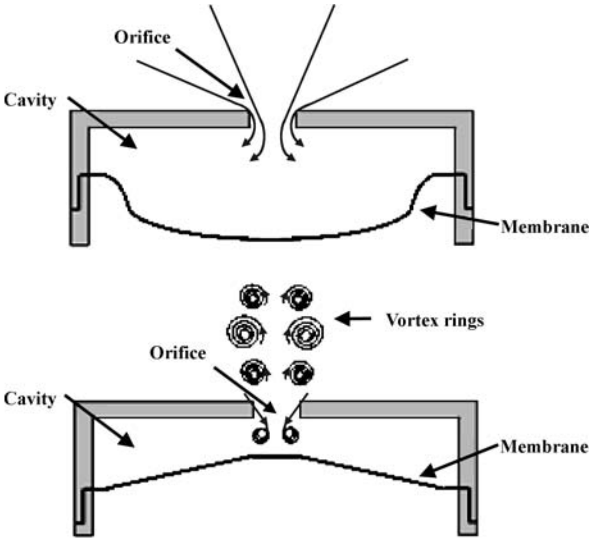
Basic Methodology

The physical configuration and the micro-fabrication procedure of microsynthetic jet, microballoon and microflap actuators are discussed in this section.

Micro Synthetic Jet

Configuration

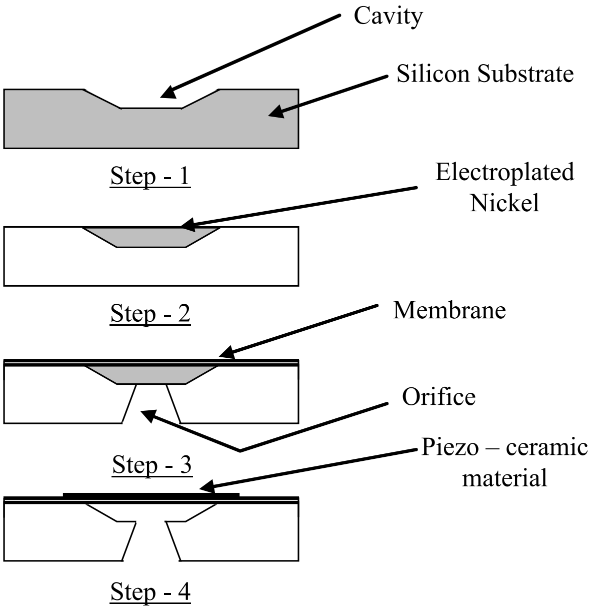
The schematic of synthetic jet is shown in Fig. 2. It consists of a cavity open to the flow through a slit or orifice. The bottom wall of the cavity is driven by a moving surface, which can be either a piston or a vibrating membrane. The vibration of the membrane can be achieved using electrostatic



Turbulence Control (Microflap, Microballoon, Microsynthetic Jet), Figure 2 Schematic of synthetic actuator with (top) ingestion and (bottom) expulsion phase

actuation, piezo-ceramic material and differential thermal expansion of the electrode material with silicon layer underneath. When the membrane or piston moves inward of the cavity, fluid is pushed out of the cavity and when the membrane or piston moves back, the fluid is sucked into the cavity. The nature of flow through the slit opening depends on; (a) the frequency of membrane oscillation, (b) the amplitude of the membrane displacement, (c) the size of the orifice and (d) the geometry of the orifice. When the movement of the membrane or piston is small the flow through the slit is reversible during ingestion and expulsion phase. Above an amplitude threshold, the flow through the slit generates acoustic or pressure wave similar to a loud speaker. With subsequent increase in the membrane or piston displacement above a threshold, the outflow separates at the exit corner and a vortex ring moving away from the orifice is formed (see Fig. 2). The jet flow from the orifice draws fluid from the adjacent surroundings contrary to the uniform inward flow during the ingestion phase. Hence, the jet provides a net point source of momentum to the flow. The synthetic jet has zero net mass flux contrary to a normal jet. It imparts a net momentum to the flow without adding any net mass to the system. There is no need of reservoir or piping system for the operation of a synthetic jet. Temporal frequency of the order of 4 kHz can be achieved for a microsynthetic jet. The spatial resolution of the microsynthetic jet depends on the orifice diameter which is of the order of 500 μm. However, the combination of the oscillating membrane size and the substrate increase the overall dimension of the microsynthetic jet limiting the capability of distributed control using multiple actuators.

T



Turbulence Control (Microflap, Microballoon, Microsynthetic Jet), Figure 3 A possible fabrication procedure of μ-synthetic Jet

Fabrication

A possible procedure for synthetic jet fabrication has been shown in Fig. 3. The first step in the fabrication process is the wet etching of the silicon wafer using KOH to form a cavity. The cavity is filled with electroplated Nickel in the second step. A polyimide membrane is deposited over the silicon wafer using spin coating in the third step. The back side of the silicon substrate is etched using KOH to obtain the orifice hole. The orifice hole extends till the filled Nickel inside the cavity and the Nickel material is also etched away. The piezo-ceramic material is deposited on top of the membrane for actuation. In case of electrostatic based actuation, aluminum electrode is deposited on the membrane. The disadvantage of the KOH based wet etching is the limited possible control over the size and shape of the orifice. To have superior control on the dimensional and shape accuracy, dry reactive etching is preferable.

Micro Balloon

Configuration

The schematic of a micro-balloon actuator is shown in Fig. 4.

This consists of Silicone rubber with manifold underneath for pressurized air actuation. The actuation takes place by the deformed shape of the silicone rubber, which is a function of the actuator pressure. The compression and decompression is achieved by a solenoid valve with external compressed air supply. Each micro-balloon consists of about 120 μm thick silicon membrane over two/three holes on a silicone chip. The bottom of Fig. 4 shows the shape and deflection of a balloon actuator at two different pressure levels. The advantage of these actuators is that they can support very large force (> 100 mN) and actuation length (> 1 mm). A micro-balloon can be operated for about 11,000 cycles of inflation and deflation and is robust against harsh environment. The disadvantage of micro-balloon actuators is the low-step response. The other disadvantage is the plastic deformation of the membrane due to stretching at high load. The actuation can be based on micro coil, piezoelectric, electrostatic and electromagnetic principle.

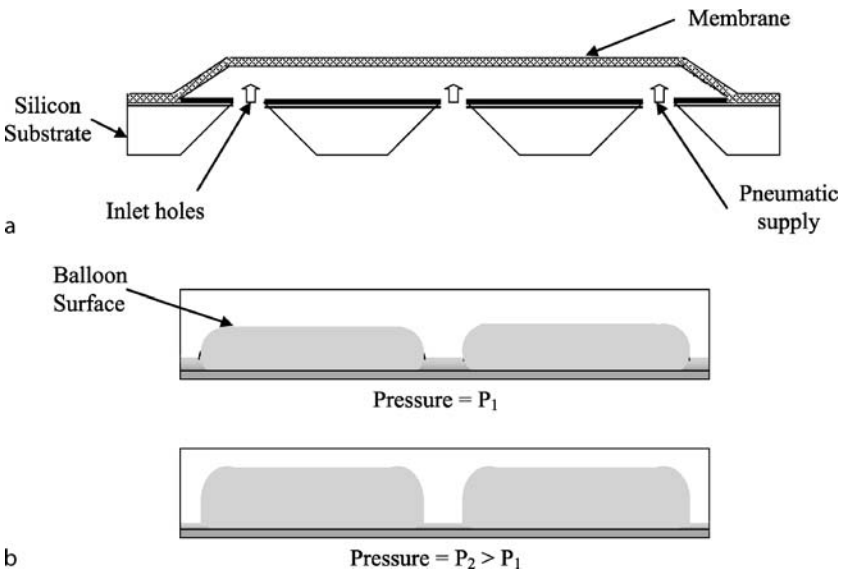
Fabrication

A possible fabrication procedure of the micro-balloon actuator has been shown in Fig. 5. In first step of the fabrication, silicon nitride is deposited using LPCVD (Low Pressure Chemical Vapor Deposition) technique at both sides of the silicon wafer. The back side of the wafer is patterned using reactive ion etching. In the second step, the cavities are etched using KOH based wet etching procedure. In the third step, Parylene-C is deposited on the front side and patterned using oxygen plasma. Parylene-C is used here to act as an intermediate layer between the silicon rubber and the sacrificial materials during the fabrication process. This is required as the sacrificial materials as oxide, silicon, photo-resist and etchants are incompatible with silicone membrane. Before removing the photo-resist, the front side of the wafer is roughened using SF_6/O_2 plasma. The photo-resist is removed and silicone rubber is spin coated on the front side of the wafer in the fourth step. In the fifth step, silcone nitride and Parylene-C are removed from the back side of the wafer using SF_6/O_2 plasma followed by O_2 plasma etching. In the last step, pressurized compressed air is sent through the cavity to release the membrane.

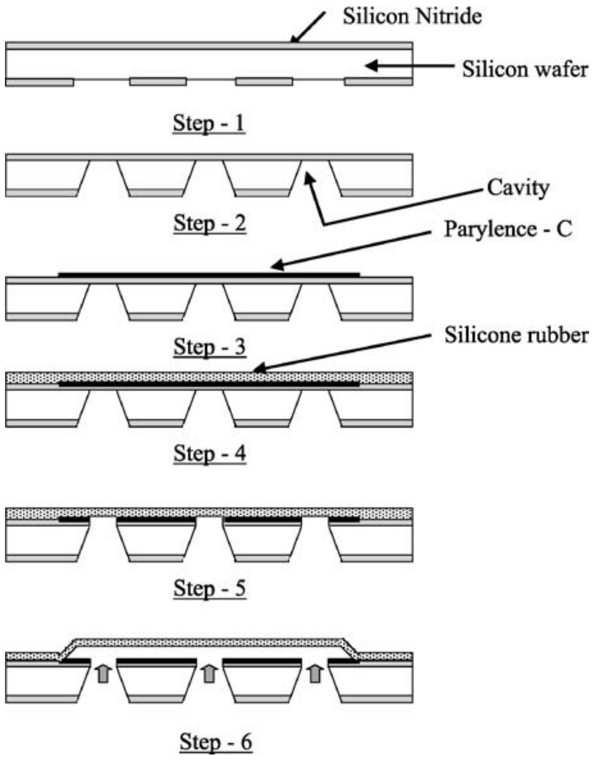
Micro Flap

Configuration

The schematic of flap actuator is shown in Fig. 6. The actuator surface is supported at one end as cantilever support and the actuation takes place due to the external applied force at the other end. The disadvantage of micro coil, piezoelectric and electrostatic actuation is the large voltage requirement. Thus, the devices heat up leading to increase in temperature of the substrate with parasitic heat loss to the fluid. Magnetic



Turbulence Control (Microflap, Microballoon, Microsynthetic Jet), Figure 4 (**a**) Schematic of a balloon actuator and (**b**) the picture of a deformed balloon actuator at two different pressure levels



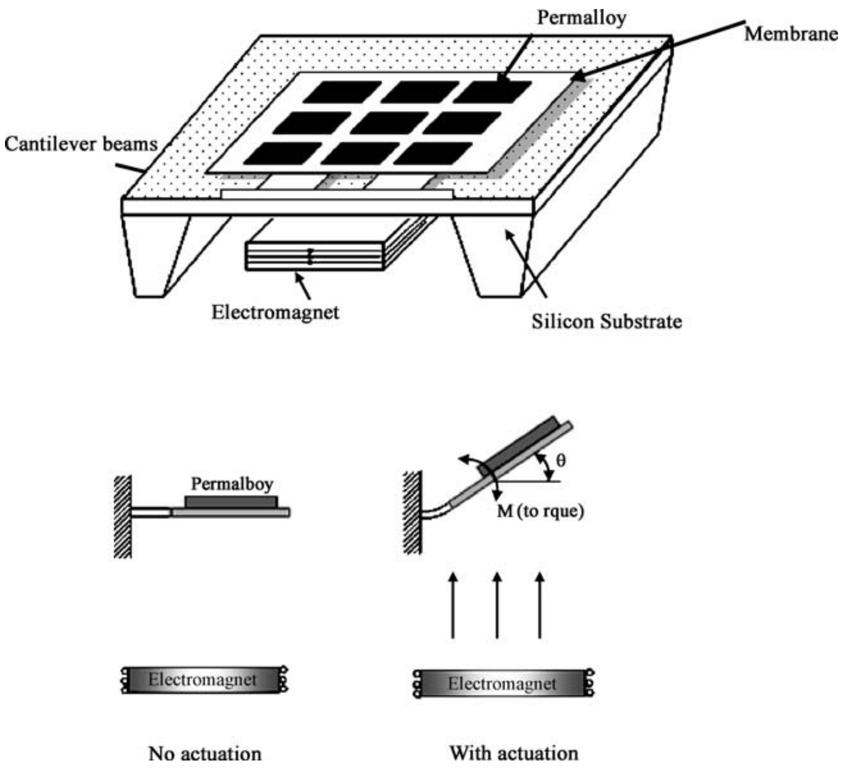
Turbulence Control (Microflap, Microballoon, Microsynthetic Jet), Figure 5 Fabrication procedure of a micro balloon actuator

actuation can achieve large force (order of hundreds μN) and large displacement (tens-hundreds of μm). The actuator consists of suspended magnetic piece supported by cantilever beams. The benefit of magnetic actuation is that magnetic field can be applied externally without any required electrical connections for voltage supply.

Silicon, silicon nitride, silicon elastomer and polymer etc. have been used as flap/membrane materials in literature One mode of operation is the application of current through the coil over electromagnet consisting of thin film coil with current passing through it. The other mode of operation is using a flap fabricated from a permanent magnet (permalloy) and actuated by an external magnetic field. During the rest mode, no magnetic field is applied and the membrane is flushed with the wall. When external magnetic field is applied by using either a permanent magnet or electro magnet, the flaps on the membrane surface are magnetized and a torque is generated due to the interaction between the internal and external magnetic field (see Fig. 6, bottom). The application of torque on the cantilever leads to deflection of the membrane/flap. The strength of the external magnetic field controls the deflection of the flap membrane. The frequency of the voltage supply to the electromagnet can be controlled for dynamic actuation.

Fabrication

The fabrication procedure of a magnetic flap actuator is shown in Fig. 7. The details on the fabrication procedure can be found in Liu et al. [4]. In the first step, phosphosilicate glass sacrificial thin film is deposited on top of the silicon substrate. This thin film is patterned to form mesas on which the actuator will be deposited. The mesas help in



Turbulence Control (Microflap, Microballoon, Microsynthetic Jet), Figure 6 Schematic of a magnetic flap actuator

limiting the possible undercut during the etching process. The photoresist layer is removed and the wafer is annealed in nitrogen at 1000°C for one hour. Subsequently, a layer of LPCVD polycrystalline silicon is coated on which thin phosphosilicate glass layer is deposited for doping purpose. Annealing at 950°C in nitrogen for one hour is carried out next for stress relieving and doping. Conductive seed layer (200 Å thick cromium and 1800 Å thick copper) is thermally evaporated in step 2. The permalloy (80% nickel and 20% iron) piece is electroplated in the third step. During electroplating, the wafer is affixed to the cathode and a pure Ni piece acts as anode. An external magnet is applied with the field lines being parallel to the wafer substrate. This establishes the easy axis of the permalloy parallel to the length of the cantilever beams. In step 4, the photoresist material is removed. The exposed seed layer material is than etched away. For etching copper, etchant (water : acetic acid : hydrogen peroxide) is used. For cromium etching, etchant (water : HCL = 10 : 1) is used. In the final fifth step, HF etching is used for about 20 minutes to release the actuators. The sacrificial layer is removed by etching and there is little effect on polysilicon. The permalloy sustains no structural and chemical damage.

Key Research Findings

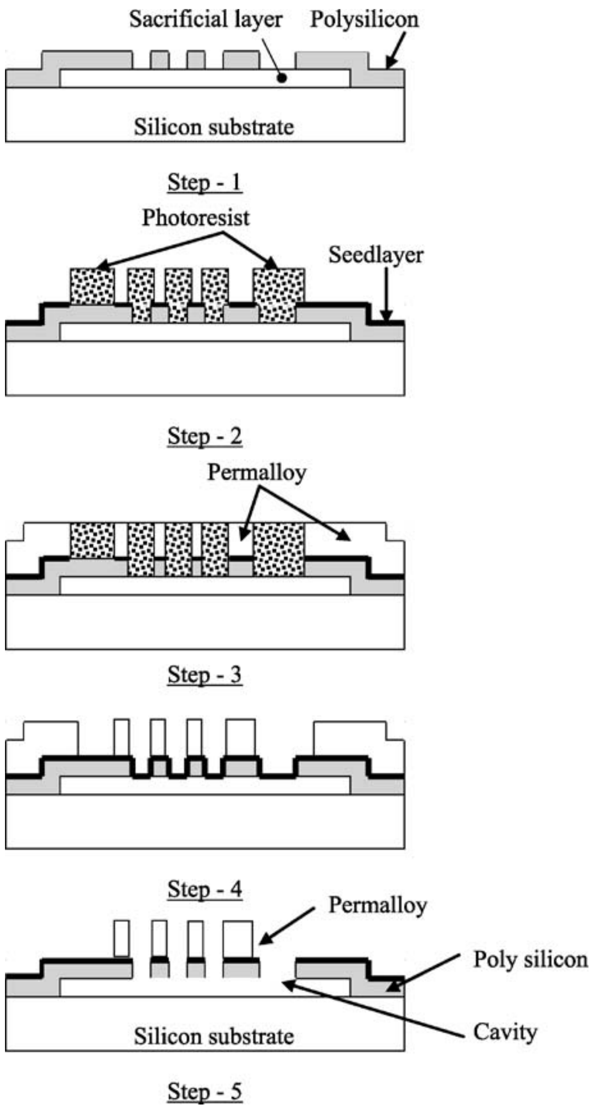
The operational characteristics and salient examples of microsynthetic jet, microballoon and microflap applications have been discussed in the following sections.

Micro Synthetic Jet Characteristics

Different non-dimensional numbers and their critical value characterize the operation of a microsynthetic jet. Reynolds number and Stokes number are used to describe the viscous and unsteady effects respectively. The Reynolds number (Re) is defined based on the maximum jet velocity, U at the exit of the orifice and orifice diameter (d) as (see Fig. 2):

$$\mathrm{Re} = \frac{Ud}{\nu} \tag{1}$$

where, ν is the kinematic viscosity of the fluid. When the jet Reynolds number is less than a critical value of about 50, the flow is reversible. For this case, the flow is identical during suction and blowing phase. When the Reynolds number exceeds the critical Reynolds number, the jet separates from the orifice edge. The Stokes number (Stk) is



Turbulence Control (Microflap, Microballoon, Microsynthetic Jet), Figure 7 Fabrication procedure of a magnetic flap actuator

defined as:

$$\mathrm{Stk} = \sqrt{\frac{\omega d^2}{\nu}} = \sqrt{\frac{d^2}{\delta_v^2}} \tag{2}$$

where, ω is the oscillation frequency of membrane and δ_v is the thickness of the unsteady boundary layer. Stokes number is the ratio between the orifice diameter and the thickness of the boundary layer at the exit of the orifice. When Stk is large, the viscous effect is not significant. When Stk is small, the viscous effect dominates and the exit velocity from the orifice reduces. This phenomenon is known as *viscous choking*. The increase in orifice size minimizes the viscous effect; but there is a simultaneous reduction in the exit velocity due to large flow area. Hence, a compromise solution is essential for the design of the micro-synthetic jet. The ratio between the square of the Stokes number and Reynolds number is known as Strouhal number (St):

$$\mathrm{St} = \frac{\omega d}{U} \tag{3}$$

The high value of Strouhal number indicates that the number of membrane cycle is higher than the frequency of fluid element passage through the orifice. The low Strouhal number value indicates similar actuation cycle of the actuator and the fluid element. Low Strouhal number indicates higher strength of the jet with low viscous losses. The *stroke ratio* which is defined as the ratio of the expelled stroke (L) to the diameter of the orifice (d) is also used to characterize the vortex ring formation of a synthetic jet. At higher stroke ratio (L/d), the vortex ring formed is disconnected from the trailing jet and at lower stroke ratio only single vortex ring is formed. The transition between these two cases is known as *formation number* and is usually within the range of 3.6 – 4.5.

The stroke ratio $L/d = U/(\omega d)$ is equal to the inverse of the Strouhal number. However, the limitation of stroke ratio definition is the assumption of slug-velocity profile. Holman et al. [2] discussed the formation criteria of synthetic jet based on both numerical simulation and experiment. They observed that vortex ring needs to withstand the suction velocity during ingestion stroke which is a function of the vortex strength. From dimensional reasoning, they proposed the following criterion for jet formation:

$$\frac{\mathrm{Re}}{\mathrm{Stk}^2} = \frac{1}{\mathrm{St}} > K \tag{4}$$

The above equation indicates that vortex escapes when the Strouhal number is less than a critical value. The constant K is a function of orifice geometry, the aspect ratio of the orifice, the shape of the exit edge i. e. sharp or rounded. The constant (K) is approximately equal to 1.0 and 0.16 for two-dimensional and axisymmetric synthetic jet respectively. Figure 8 shows the vorticity distribution during the ingestion and expulsion phase of a synthetic jet. The no-jet case corresponds to the K value less than 1.0 and the jet formation case corresponds to K value greater than 1.0 for a two-dimensional synthetic jet. For the jet formation case, the separated vortex ring is not dragged into the cavity during the ingestion stroke leading to a net momentum transport to the flow. Figure 8 compares the Reynolds number versus Stokes number relationship between the jet and no-jet formation case from both experimental and theoretical data (Holman et al. [2]). The small discrepancy between

the two is attributed to the orifice geometry or curvature effect.

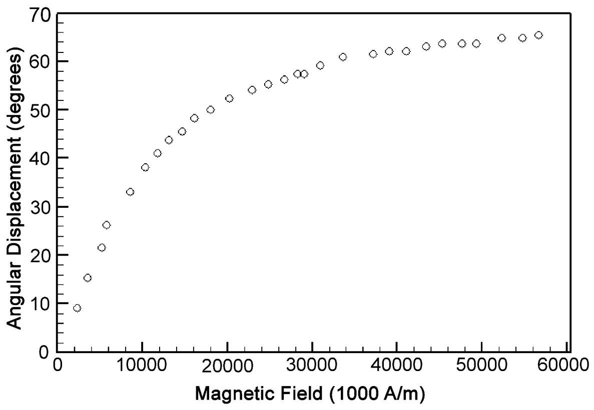
Lee et al. [8] presented the effectiveness of micro-synthetic jet for modification of turbulent boundary layer under adverse gradient. They showed significant mixing enhancement of the boundary layer when the forcing frequency is closer to the natural instability frequency. The boundary layer modification is more sensitive to forcing frequency compared to the forcing amplitude. The near wall mean velocity and turbulence intensity are significantly enhanced due to the operation of the synthetic jet. The synthetic jet needs to have sufficient velocity output and strong longitudinal vortices for effective flow control.

Micro Balloon Characteristics

The deflection of a micro balloon actuator depends on the actuation air pressure. Figure 9 shows the deflection versus pressure relationship of a silicone based balloon actuator. It shows the direct relationship between the applied pressure and the deflection. The plastic deformation of the balloon and the effect due to cyclic variation is used to decide the operating range of the micro balloon. Tung et al. [6] investigated the compressible flow separation control of a three-dimensional wing section using micro-balloon actuators. A glass plenum was used for supply of compressed air to the balloons. An initial pressure was applied for overcoming the stiction of the diaphragm to the substrate. The balloon deflection of about 1.2 mm was obtained during the testing experiment. The actuation pressure was varied between 4.5 to 7.5 psig depending on the Mach number of the flow. The micro-balloon actuator was shown to be successful in control of separation characteristics. A large pressure recovery was observed during the activation of the micro-balloon actuator. However, the shear stress sensors showed reduction in lift to drag ratio due to the micro-balloon actuation indicating the necessity of proper optimization of control technique. The micro-balloon was shown to be robust demonstrating its ability for high speed flow control applications.

Micro Flap Characteristics

Liu et al. [4] investigated the effect of micro-flap actuator on a delta wing airfoil. The flap was 400 µm long and 100 µm wide. The calibration of the flap actuator was carried out in still air. An electromagnet was used to provide uniform external magnetic field. The magnetic field intensity was measured using Gauss meter. The angular displacement with respect to the magnetic field intensity is shown in Fig. 10. Large angular deflections (about 60 deg) and vertical deflections (about 1 – 2 mm) was demonstrated. It shows the asymptotic variation of flap displacement angle with respect to the magnetic filed



Turbulence Control (Microflap, Microballoon, Microsynthetic Jet), Figure 10 Angular displacement versus magnetic field strength of a flap actuator

intensity. Arrays of flaps positioned near the leading edge of delta wing showed generation of rolling moment by flap actuation. The effect of actuator location on the rolling moment of the delta wing was investigated from the force balance. Clear effect on rolling moment as a function of the actuator location was observed. The flow visualization images showed the vortical structures generated by the actuator.

Future Directions for Research

The micro actuators have shown success in various flow control applications. The detailed criteria for characterization of successful synthetic jet formation are evolving. There are limited data on the synthetic jet formation constant as function of the geometric parameters of the synthetic jet. The universality of jet formation constant needs to be verified for variety of synthetic jet geometries. The size, strength and trajectory of the vortices from synthetic jet need to be characterized from more detailed measurements and analysis. The effect of multiple synthetic jets, the pitch between neighbouring jets and the relative phase difference need to be investigated with respect to the nature of control vortices formation. The efficacies of flap actuators have been demonstrated in axisymmetric jet control and delta wing manoeuvring applications. The micro balloon actuators have shown its receptiveness to boundary layer control over delta wing with limited success on drag reduction. The integration and implementation of appropriate electronics with the micro actuator have not received adequate attention. The integration of microelectronics and micro-actuators with optimal control strategy will improve the performance of turbulent flow control applications. The uniformity in characterization and fabrication procedure of the micro actuators will facilitate their widespread research and industrial applications in future. The efficacy of these micro actuators for micro fluidics applications needs to be further explored.

Definition

Fluid flows can be generally described as being either laminar or turbulent. As opposed to laminar flows, in which the fluid moves in smooth layers (or laminae), turbulent flows are characterized by chaotic motion of fluid elements and seemingly random fluctuations in instantaneous velocities. One result of the chaotic fluid motion in turbulent flows is a tremendous increase in heat and mass transfer compared to laminar flows.

Overview

The governing equations for viscous fluid flow are conservation of mass (or continuity) and the Navier–Stokes equations (conservation of momentum or Newton's Second Law applied to a fluid). For steady-state, incompressible flow, these equations can be written as

$$\nabla \cdot \boldsymbol{u} = 0 \tag{1}$$

$$\rho\,(\boldsymbol{u} \cdot \nabla)\,\boldsymbol{u} = -\nabla p + \mu \nabla^2 \boldsymbol{u} \tag{2}$$

where $\boldsymbol{u}$ is the velocity, ρ is the fluid density, p is the pressure, and μ is the fluid viscosity. By introducing a characteristic length, L, a characteristic velocity, U, and a characteristic pressure, p_0, Eqs. (1) and (2) can be rendered dimensionless, resulting in

$$\nabla \cdot \boldsymbol{u}^* = 0 \tag{3}$$

$$\rho^* \left(\boldsymbol{u}^* \cdot \nabla\right) \boldsymbol{u}^* = -\mathrm{Eu}\nabla p^* + \frac{1}{\mathrm{Re}} \nabla^2 \boldsymbol{u}^* \tag{4}$$

where $()^*$ indicates a dimensionless quantity, $\mathrm{Eu} = p_0/(\rho U^2)$ is the Euler number, and $\mathrm{Re} = (\rho U L)/\mu$ is the Reynolds number.

The Reynolds number is the most important dimensionless parameter in fluid dynamics. Physically, the Reynolds number represents the ratio of inertial forces to viscous forces, and thus quantifies the effects of viscosity in the flow. In a pipe or channel flow, the characteristic velocity is typically taken as the mean velocity, and the characteristic length is typically taken as the pipe diameter or channel width.

In turbulent flows, Re is important because it can be used to determine when the flow transitions from laminar to turbulent flow and also when the flow achieves a fully turbulent state. For macroscale pipe and channel flows, transition to turbulence can occur in the range $1800 < \mathrm{Re} < 2300$, depending of flow conditions, and the flow becomes fully turbulent at a Reynolds number of approximately 4000. As will be shown later in this chapter, whether flows in microchannels agree with this macroscale behavior has long been a topic of debate, as some researchers have reported transitional Reynolds numbers in microchannel flows far lower than the $1800-2300$ reported for macroscale flows. However, recent studies using newly developed experimental techniques and also careful reexamination of the results of some of the earlier studies strongly suggest that microchannel flows do indeed exhibit transitional behavior similar to that observed in macroscale flows.

In designing systems involving pipes or channels, one important consideration is the pressure drop due to fluid friction for a pipe or channel, as this determines the pumping power required to force fluid through the conduit. The pressure drop, Δp, due to fluid friction with the pipe or channel walls can be found using

$$\Delta p = f \rho \frac{\ell}{D_\mathrm{h}} \frac{U^2}{2} \tag{5}$$

where ℓ is the pipe or channel length, D_h is the hydraulic diameter (calculated using $D_\mathrm{h} = \frac{4A}{P_W}$, where A is the cross-sectional area and P_W is the wetted perimeter), U is the mean velocity, and f is the Darcy friction factor. For laminar flow, f is purely a function of the Reynolds number, such that

$$f = \frac{64}{\mathrm{Re}} \tag{6}$$

For turbulent flows, the friction factor is a function of both the Reynolds number and the relative roughness, $\frac{\varepsilon}{D_\mathrm{H}}$, where ε is the root mean square roughness of the pipe or channel walls. For turbulent flows, the friction factor is found experimentally. The experimentally measured values for friction factor as a function of Re and $\frac{\varepsilon}{D_\mathrm{H}}$ are compiled in the Moody chart [1]. Whether the macroscale correlations for friction factor compiled in the Moody chart apply to microchannel flows has also been a point of contention, as numerous researchers have suggested that the behavior of flows in microchannels may deviate from these well established results. However, a close reexamination of previous experimental studies as well as the results of recent experimental investigations suggests that microchannel flows do, indeed, exhibit frictional behavior similar to that observed at the macroscale. This assertion will be addressed in greater detail later in this chapter.

In analyzing turbulent flows, it is often convenient to decompose the instantaneous velocity components and the pressure into mean and fluctuation components, such that

$$u = \langle u \rangle + u', \qquad v = \langle v \rangle + v',$$
$$w = \langle w \rangle + w', \qquad p = \langle p \rangle + p'$$

where $\langle\rangle$ denotes an ensemble average. Introducing these quantities into the Navier–Stokes equations and taking the ensemble average yields the Reynolds-averaged Navier–

Stokes (RANS) equations, which are

$$\rho\left(\langle u\rangle\frac{d\langle u\rangle}{dx}+\langle v\rangle\frac{d\langle u\rangle}{dy}+\langle w\rangle\frac{d\langle u\rangle}{dz}\right)=-\frac{\partial\langle p\rangle}{\partial x}+\mu\nabla^2\langle u\rangle-\rho\left(\frac{\partial\langle u'u'\rangle}{\partial x}+\frac{\partial\langle u'v'\rangle}{\partial y}+\frac{\partial\langle u'w'\rangle}{\partial z}\right)$$
$$\rho\left(\langle u\rangle\frac{d\langle v\rangle}{dx}+\langle v\rangle\frac{d\langle v\rangle}{dy}+\langle w\rangle\frac{d\langle v\rangle}{dz}\right)=-\frac{\partial\langle p\rangle}{\partial y}+\mu\nabla^2\langle v\rangle-\rho\left(\frac{\partial\langle u'v'\rangle}{\partial x}+\frac{\partial\langle v'v'\rangle}{\partial y}+\frac{\partial\langle v'w'\rangle}{\partial z}\right)$$
$$\rho\left(\langle u\rangle\frac{d\langle w\rangle}{dx}+\langle v\rangle\frac{d\langle w\rangle}{dy}+\langle w\rangle\frac{d\langle w\rangle}{dz}\right)=-\frac{\partial\langle p\rangle}{\partial z}+\mu\nabla^2\langle w\rangle-\rho\left(\frac{\partial\langle u'w'\rangle}{\partial x}+\frac{\partial\langle v'w'\rangle}{\partial y}+\frac{\partial\langle w'w'\rangle}{\partial z}\right) \tag{7}$$

The terms of the form $\langle u'_i u'_j\rangle$ are called the Reynolds stresses. The RANS equations do not consist of a closed set of equations (there are more unknowns than equations), so if the RANS equations are to be solved, the Reynolds stress terms must be modeled somehow. Typically, this modeling is based on experimental measurements. The application of models developed for macroscale flows to turbulent microchannel flows is dependent on the Reynolds stresses being similar for both cases. Recent experimental evidence suggests a strong similarity between turbulence statistics measured in turbulent microchannel flows and turbulence statistics measured in turbulent pipe and channel flows. Thus, the evidence suggests that turbulent models and codes developed to study macroscale turbulent pipe and channel flow should be applicable to the study of turbulent microchannel flows.

While the fluctuating velocities in turbulent channel flow may seem to imply random motion in the fluid, in actuality, turbulent channel flows (and turbulent flows in general) do contain underlying structure. One characteristic of turbulent flows is the presence of large- and small-scale turbulent eddies. One way to describe these turbulent structures of the flow is to measure spatial correlations of velocity fluctuations and to define characteristic length scales of the turbulent structures.

The normalized spatial correlation of the fluctuating velocity component u'_i with the fluctuating velocity component u'_j is defined as

$$R_{u'_i u'_j}(\Delta\boldsymbol{x};\boldsymbol{x})=\frac{u'_i(\boldsymbol{x})\,u'_j(\boldsymbol{x}+\Delta\boldsymbol{x})}{\sqrt{\langle u'^2_i(\boldsymbol{x})\rangle}\sqrt{\langle u'^2_j(\boldsymbol{x})\rangle}}$$

Where $\boldsymbol{x}$ is some location in the flowfield, and $\Delta\boldsymbol{x}$ is a displacement vector from location $\boldsymbol{x}$. If the turbulent velocity field was truly random, then $R_{u'_i u'_j}(\Delta\boldsymbol{x};\boldsymbol{x})$ would be equal to zero for all $\Delta\boldsymbol{x}\neq 0$. However, in a turbulent flow, $R_{u'_i u'_j}(\Delta\boldsymbol{x};\boldsymbol{x})$ is not equal to zero, signifying the existence of underlying structure in the turbulent flow. The properties of $R_{u'_i u'_j}(\Delta\boldsymbol{x};\boldsymbol{x})$ can be used to discern some characteristics about this underlying flow structure.

For example, $R_{u'_i u'_j}(\Delta\boldsymbol{x};\boldsymbol{x})$ can be used to define characteristic length scales for the underlying turbulent structures. $R_{u'_i u'_i}(\Delta\boldsymbol{x};\boldsymbol{x})$ has the property of being equal to 1 at $\Delta\boldsymbol{x}=0$ and approaching zero as $\Delta\boldsymbol{x}\to\infty$. The integral length scale for a turbulent flow is defined as

$$L_i=\int_0^\infty R_{u'_i u'_i}(\Delta\boldsymbol{x};\boldsymbol{x})\,d\Delta\boldsymbol{x}$$

One way to compare the turbulent structures present in microchannel flows with the turbulent structures present in turbulent macroscale pipe and channel flows is to compare the integral length scales for each. As will be shown in the next section, the integral length scales of turbulent microchannel flows agree well with the integral length scales for their macroscale counterparts, suggesting that turbulent microchannel flows and large-scale pipe and channel flows are structurally similar.

In summary, even though the characteristic length scales of turbulent flows in microchannels are several orders of magnitudes smaller than their counterparts in macroscale pipes and channels, experimental evidence suggests the flows are statistically and structurally similar. As such, long established correlations for pressure drop in pipes and channels, and computational tools available for the study of turbulent pipe and channel flows should be equally applicable to turbulent microchannel flows.

T

Key Research Findings

Transition to Turbulence

In early studies of flow in microchannels, the onset of transition to turbulence was inferred from measurements of bulk properties of the flow, such as pressure drop or heat transfer rate. The behavior of the friction factor or Nusselt number undergoes a drastic change when the flow transitions to turbulence, and thus an observation of such a behavioral change can be indicative of the onset of turbulent flow.

Many of these early studies of flow in microchannels suggested transition to turbulence occurring at lower Reynolds numbers than those observed at the macroscale. For example, Wu and Little [2] measured friction factors and Nus-

selt numbers of gas flow through etched microchannels with D_H ranging from 45 μm to 83 μm, and their results suggested an early onset of transition occurring at around Re = 350. Similarly, Pent et al. [3] measured the friction factors and Nusselt numbers of flow through stainless steel microchannels of various diameters and aspect ratios and observed behavior consistent with transitional Reynolds numbers ranging from 200 – 700. Evidence of early transition to turbulence was also suggested by other experimental studies, too numerous to list individually here.

One common conclusion of many of these early studies was that the relatively high surface roughness of the microchannels investigated was a major factor in the observed behavior. However, this explanation is unsatisfying because there have also been researchers whose results on transition similarly derived from friction factor and Nusselt number data agreed well with macroscale behavior for microchannels with the same magnitude of relative roughness as the researchers mentioned previously. For example, in experiments on microchannels with hydraulic diameters ranging from 112 μm to 210 μm and aspect ratios from 1.0 to 1.5, Hegab et al. [4] reported transition for Re over 2000. Similarly, Qu and Mudawar [5] found no evidence of early transition in a series of micro heat sink experiments with Reynolds numbers as high as 1672. Transitional Reynolds numbers consistent those at the macroscale have also been observed by numerous other researchers.

In an attempt to clarify the seemingly contradictory results on transition in microchannels presented by various researchers, Hetsroni et al. [6] reexamined the results of previous researchers, with a particular emphasis on determining possible sources of the anamoulous results found in some studies. They determined that the anamoulous results reported by some researchers were due to either improperly defined experiments, heating of the fluid due to viscous dissipation resulting in a change in fluid viscosity, or due to measurement error. After examining the extensive body of experimental studies on transition in microchannels, they concluded that the vast preponderance of evidence reveals that the transitional behavior of flow in microchannels shows no differences with macroscale flow.

The recent development of microscopic particle image velocimetry (microPIV) [7] has provided researchers with the capability of measuring instantaneous velocity fields in microchannels, and hence provided an additional tool for investigating transition in microchannels. Because microPIV can be used to directly observe features of the velocity field in the microchannel, data collected using this technique provide a more direct indication of transition than pressure drop measurements where the transitional behavior must be inferred. In the first study of transition using microPIV, Sharp and Adrian [8] measured velocities in round microtubes with diameters between 50 μm and 247 μm. Using an increase in the root-mean-square velocity fluctuations along the centerline of the microtube as an indication of transition to turbulence, Sharp and Adrian observed transition between $1800 < \mathrm{Re} < 2300$, and thus concluded that early transition did not occur.

Li and Olsen used microPIV to measure velocity fields in microchannels for Reynolds numbers ranging from 272 to close to 3000 in two sets of experiments. In the first set of experiments [9], Li and Olsen measured velocity fields in square cross-section microchannels with hydraulic diameters ranging from 200 μm to 640 μm, and in the second set of experiments [10], they repeated these measurements for microchannels with hydraulic diameters equal to 480 μm and aspect ratios ranging from 0.97 to 5.69. In both sets of experiments, they observed transition in the same range of Reynolds numbers as Sharp and Adrian, indicating transitional behavior in agreement with classical macroscale results.

To summarize, although the transitional behavior of microchannel flows has been a point of significant debate due to conflicting results reported by numerous investigators, a close reexamination of the previous studies and the recent addition of microchannel velocity measurements using microPIV have strongly suggested that microchannel flows exhibit the same transitional behavior as has been observed in macroscale pipes and channels.

Friction Factor in Turbulent Microchannel Flow

Whether the friction factor for flow in microchannels agreed or disagreed with classical macroscale results was also long a point of confusion due to conflicting experimental results. Several of the early studies of flow in microchannels, including those of Wu and Little [2], measured friction factors that were significantly greater than well accepted macroscale results. However, numerous other researchers, including Qu and Mudawar [5] reported good agreement between microscale and macroscale friction factors. The study of Judy et al. [11] is particularly of interest due to its breadth. Judy et al. measured friction pressure drop of fluid flow in microtubes and microchannels with hydraulic diameters between 15 μm and 150 μm for three different fluids (water, methanol, and isopropanol), two different tube materials (and hence two different surface roughnesses), and two different tube cross-sectional geometries (circular and square), and found no significant deviation from macroscale viscous flow theory.

Hetsroni et al. [6] also reexamined previous studies of friction factor in microchannels and drew the same conclusions that they did for transition in microchannels. They found that the anamoulous results reported in some studies could be explained by the same factors that contributed to the observation of anamoulous transitional behavior. Indeed, in the only study performed to date combining both microPIV and extensive pressure drop measurements, Sharp and Adrian [8] found that transition as measured by microPIV agreed well transition as inferred from friction factor data, and also found that their measured friction factors agreed well with macroscale results. As with transition to turbulence, the experimental evidence on friction factors in turbulent microchannel flow shows that microscale flow exhibits the same behavior as macroscale flows.

Turbulence Statistics and Large-Scale Structures

The studies referenced up to this point indicate that the bulk characteristics of turbulent microchannel flow, specifically the onset of transition and the frictional pressure drop, tend to agree well with classical results for macroscale pipe and channel flow. However, the question remains as to whether the microscale turbulence is statistically and structurally similar to turbulence at the macroscale.

The development of microPIV as a microfluidics research tool has made it possible to measure statistical quantities such as velocity fluctuations and Reynolds stresses. Moreover, since microPIV provides instantaneous *velocity field* data, spatial correlations of velocity fluctuations can be measured, yielding insights into the underlying large scale structures in turbulent microchannel flow. However, obtaining reliable microPIV data in turbulent microscale flows is inherently difficult, and thus, to the author's knowledge, at the present time only two research groups have been successful in obtaining *whole-field* turbulence data for turbulent flow in microchannels. The major research findings of these studies are summarized below.

Velocity Fluctuations and Reynolds Stresses

Li and Olsen [9, 10] were the first researchers to measure profiles of velocity fluctuations in turbulent microchannel flow. They measured streamwise and transverse velocity fluctuations and Reynolds shear stresses for a range of Reynolds numbers spanning the laminar through fully-turbulent regime. They found good agreement between their measured fluctuations and Reynolds shear stresses and values reported for macroscale turbulent duct flow.

Natrajan et al. [12] collected velocity fluctuation and Reynolds shear stress data for turbulent flow in round microtubes for Re = 4500 (well within the fully-turbulent flow regime), and compared their experimental results with the results of a direct numerical simulation of turbulent pipe flow at a comparable Reynolds number. The comparison of these results is shown in Fig. 1, with the solid lines representing the DNS results and symbols representing the microPIV results. The agreement for the streamwise velocity fluctuations is nearly exact, while the transverse fluctuations and Reynolds shear stress agree to within 10% with the DNS results (this slight discrepancy in transverse velocity fluctuations is due to limitations in PIV itself and not due to any physical differences between micro- and macro-scale turbulence. See Liu et al. [13] for similar results obtained in comparing macroscale PIV data to DNS results).

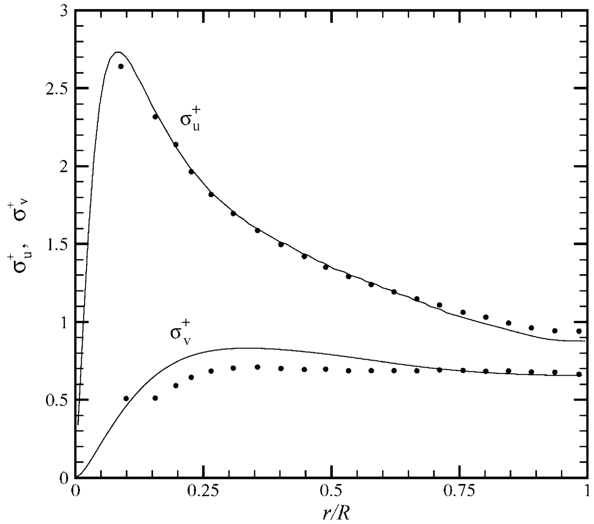
Taken as a whole, the studies of Li and Olsen and Natrajan et al. encompass flow in round microtubes, square microchannels, and rectangular microchannels with aspect ratios as high as 5.69. They suggest that, with regards to pointwise turbulent statistics, turbulent flow in microchannels over an array of microchannel geometries agree well with pointwise statistics in similar macroscale geometries.

Large-Scale Structures and Velocity Correlations

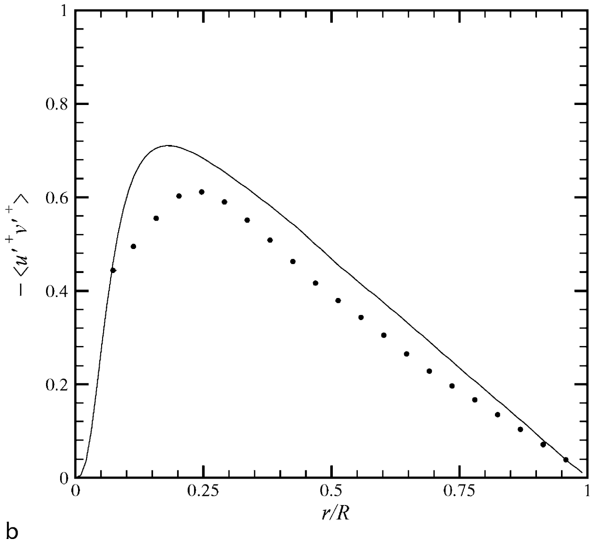
The previously mentioned microPIV studies suggest that the turbulence in microchannels is *statistically* similar to flow in macroscale pipes and channels, but it is also important to consider if the microscale flows are *structurally* similar to macroscale flows. One way to determine this is to measure the characteristics of the large-scale turbulent structures in turbulent microchannel flow and compare these to turbulent macroscale flow.

Figure 2 is an instantaneous velocity field in a 536 μm diameter microtube at Re = 4500. Large-scale turbulent eddies are clearly visible throughout the velocity field, and a comparison to a velocity field obtained in a macroscale pipe would show many similarities. However, such comparisons are qualitative only, and a true quantitative comparison can only be made by statistically comparing the large-scale structures, as can be done by calculating spatial correlations and turbulent length scales.

Li and Olsen [14] were the first to perform such calculations. They calculated spatial correlations from ensembles of instantaneous velocities fields for flows in square microchannels and defined turbulent length scales in the streamwise and transverse directions as the distance it takes normalized spatial correlations of streamwise velocity correlations to drop to 0.5. These correlation lengths in the streamwise and transverse directions were called Lx_{uu} and Ly_{uu}, respectively. A comparison of these microchannel correlation lengths normal-



a



b

Turbulence in Microchannels, Figure 1 (**a**) Rms velocity fluctuations and (**b**) Reynolds shear stress as measured by microPIV for turbulent flow in a 536 μm diameter glass microtube

ized by microchannel width, W, and correlation lengths for macroscale channels [15] are shown in Table 1. Excellent agreement was observed between the microscale and macroscale results. Natrajan et al. [12] also calculated spatial correlations from their microPIV data for turbulent microtube flow and also found excellent agreement between their results and spatial correlations for turbulent pipe flow.

While at the present time, these two studies are the only measurements of spatial correlations and turbulent length scales for microscale flows, the agreement observed in these measurements compared to large-scale pipe and channel flows suggest that the turbulence in microchannels and microtubes is structurally similar to the turbulence observed in similar macroscale flows.

Turbulence in Microchannels, Table 1 A comparison of turbulent length scales for turbulent microchannel and macroscale channel flows

Study	Channel Dimension	Re	$2Lx_{uu}/W$	$2Ly_{uu}/W$	Lx_{uu}/Ly_{uu}
Li and Olsen [14]	325 μm	2853	0.38	0.20	1.90
Li and Olsen [14]	490 μm	3489	0.34	0.17	2.00
Li and Olsen [14]	640 μm	3333	0.30	0.16	1.88
Clark [15]	25 mm	3460	0.37	0.20	1.85
Clark [15]	25 mm	8300	0.29	0.16	1.93

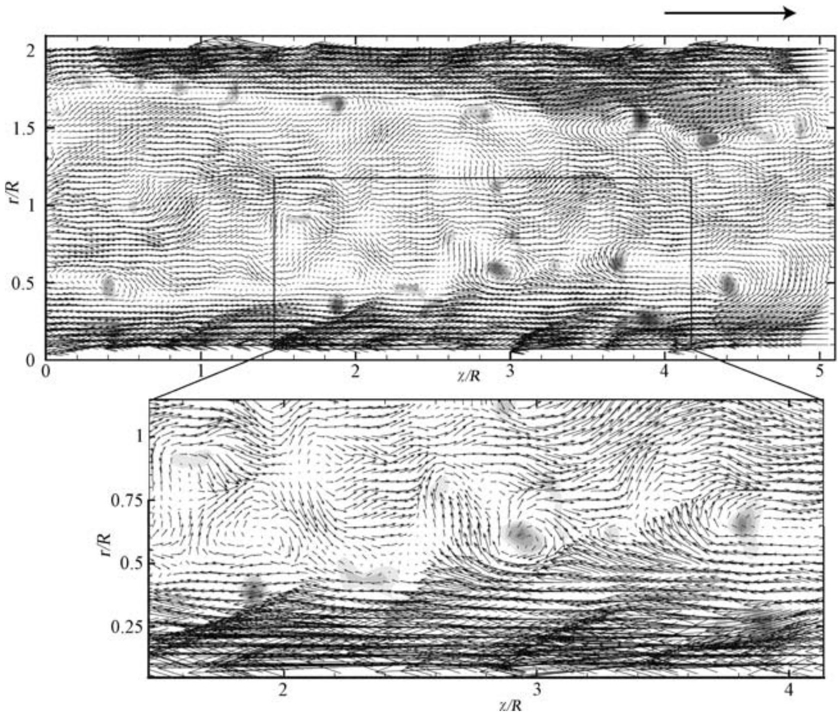
Summary of Key Research Findings

Although for many years there were some questions about whether turbulent microchannel flows exhibited behavior similar to macroscale flows, recent experiments using new experimental techniques and a reexamination of data collected in previous studies suggest that, at least for microchannels as small as 50 μm in diameter, these questions are unfounded. Turbulent microchannel flow exhibits the same transitional behavior, displays similar frictional loss characteristics, and is statistically and structurally similar to macroscale pipe and channel flow.

Directions of Future Research

The number of studies utilizing microPIV in microchannels has to this point been very limited. Moreover, thus far this small number of studies has been limited to microchannels with hydraulic diameters greater than 200 μm. While these studies strongly suggest that microchannel turbulence is statistically and structurally similar to macroscale pipe and channel turbulence, a truly definitive answer cannot be arrived at until these two studies are supplement by additional studies for smaller hydraulic diameter microchannels.

Moreover, there must be some lower limit of microchannel hydraulic diameter beyond which the fluid behavior begins to deviate from behavior observed at the macroscale. At some point, the characteristic length scale of the flow will become so small that the continuum hypothesis must break down. However, the mean free path of molecules in liquid flows in microchannels is on the order of nanometers, and



Turbulence in Microchannels, Figure 2 An instantaneous velocity field as measured by microPIV for Re = 4500 flow in a 536 μm diameter glass microtube. A convective velocity of 91% of the centerline velocity has been subtracted to help visualize turbulent structures

thus, this lower limit is likely to be significantly smaller than 1 μm. Experiments will have to be performed to determine what this lower limit is, and also to determine the characteristics of flow in this regime.

Two Phase Flow

Definition

Two phase flow is the flow of two immiscible fluids in the same micro- or nanofluidic conduits, the fluids can be of different chemical compositions – liquid/liquid, or in different physical states – gas/liquid.

Ultrasonic material removal

Definition

Removal of materials using an axially oscillating tool at ultrasonic frequency (about 20,000 Hz) with a fine abrasive of silicon carbide, aluminum oxide, or boron carbide carried by a liquid between tool and work piece.

Overview

Ultrasonic vibrations are used in various engineering applications such as cleaning, welding and machining. Ultrasonic machining (USM) is the removal of materials by abrasive bombardment and crushing in which a soft flat-ended tool is made to vibrate at a frequency of about 20,000 hertz and amplitude of 0.001 – 0.003 inch. During the vibration, bunches of hard abrasive particles are continuously fed into the machining zone, between the tool and the work piece. The particles give either direct action on the surface of work piece or cavitation erosion caused by rapid changes in pressure inside the fluid, resulting in the material removal to form the required structure [1–3]. The dimensions of the work piece are determined by the size of the abrasive particles. Micro-ultrasonic machining (μUSM) can be realized by using submicron particles. The USM process is able to machine any material, but is more efficient on brittle materials. The abrasive particles have to be harder than the work piece material.

Ultrasonic machining is mostly used for producing small details in hard materials such as glass, precious stones, ceramics and composites. Many USM applications are involved in drilling where a tool penetrates into the work piece to produce either a through or blind hole of the required dimensions [4]. By applying fine abrasive grains (0.2 μm diamond particles), the technique was successfully utilized to produce micro holes as small as 5 μm in diameter with 37 μm in depth, in glass and silicon [5]. By combining USM and other machining techniques such as wire electro-discharge grinding (WEDG) and electro-discharge machining (EDM), the fabrication of complete 3D microstructure within one total manufacturing process becomes possible, e. g. a 3D micro center-pin bearing air turbine developed by Sun, et al. [6]. Recently, the technique was further extended to the nanometer scale by using ultrasonic actuation with an Atomic Force Microscope tip, which can induce structural surface and subsurface modifications at Highly Oriented Pyrolytic Graphite and thus facilitate the patterning of nanoscale surface features [7].

There are variations on the basic USM techniques. Rotary ultrasonic machining (RUM) [8, 9] is the technique involving the vibration of a small grinding toll, which is excited and simultaneously rotated. The technique permits increase in machining speed and decrease in machining forces, a useful condition for machining with fragile tools. The same advantages of smaller forces can be obtained by applying ultrasonic vibrations to a surgical tool in various medical applications. Examples include ultrasonic assistance dental cutting, brain tumors removal and artery surgeries [9, 10].

Acoustic streaming pumps

Definition

Ultrasonic pumps are pumps that use acoustic streaming to create a fluid motion inside microchannels. Acoustic streaming is the time-averaged flow induced by an ultrasonic wave (periodic pressure oscillation). Attenuation of the acoustic energy (via reflection and other distortion) generates a body force within the fluid and converts acoustic energy into kinetic energy of the fluid [1].

Overview

Ultrasonic pumps are very useful for microscale applications due to their simplicity, robustness and scaling advantages. Moreover, they are insensitive to the chemical state of the fluid and the wall material unlike electroosmotic and magnetic pumps. By using acoustic streaming as a pumping mechanism, noncontact fluid control is achievable since no contact is needed between the acoustic source and the fluid; and no valves are required [2].

Acoustic streaming flow fields depend on acoustic beam characteristics, fluid properties and the presence and the geometry of solid boundaries or particles. Depending on these factors, laminar, transitional or turbulent flow with jets and vortices can be generated. Acoustic streaming is proportional to the sound pressure level of the acoustic beam and the square of the frequency of the acoustic wave [1]. However, excessive heating – since most of the acoustic energy becomes heat – and bubble formation set an upper limit for high intensities [2].

An ultrasonic transducer is an integrated component of acoustic pumps. The transducers that generate ultrasonic energy with megahertz frequency for ultrasonic pumps make use of the piezoelectric (PZT) effect. A PZT layer is the vital component of the ultrasonic transducer and provides the oscillatory motion that ultimately produces the acoustic beam.

Rife et al. [3] developed a fluidic pumping circuit powered by an acoustic frequency of 50 MHz, and generated fluid flow with velocities of the order of mm/s. They used ultrasonic PZT transducers for their pump to generate the acoustic waves. The intensity of the waves was low enough to produce negligible heating; however, even if the heating could be tolerated, dielectric breakdown in the PZT thin film limited the maximum intensity. They also discussed bubble formation, and concluded that for frequencies above a few megahertz, the technique was safe to use for degassed liquids without any cavitation problem.

Nguyen and White [4] presented a numerical study of a flexural plate wave (FPW) micropump. Their simulated device consisted of a channel with a thin PZT membrane, whose thickness was $1-3\ \mu m$ attached to a bottom wall. This membrane generated a high-intensity acous-

tic filed in the vicinity of the fluid inducing the motion of a fast-moving layer near the membrane. They investigated the pumping performance with different parameters such as the wave amplitude, channel height and back pressure. They concluded that micropumps with a height of a few micrometers had a good performance due to their high flow rate and high hydraulic impedance against back pressure.

No-moving-part pumps

Definition

The term, despite its common and frequent use, is actually a misnomer. The fluidic pumps so described in fact do have valves and it is the arrangement and configuration of these valves which is their most interesting aspect. What are absent are the mechanical moving or deformed components in the valves. The valves are there to rectify the alternating flow generated, as in the more conventional pumps, by an actuator performing reciprocating motions and displacing the pumped fluid from the displacement cavity. The actuators are usually driven by an electric input.

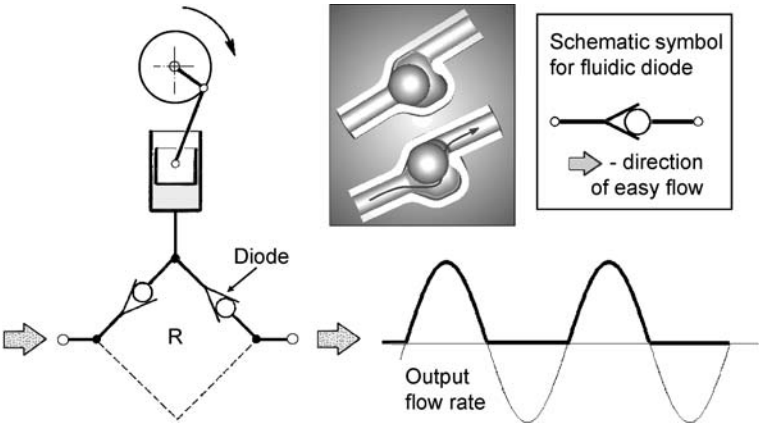
In the "valve-less" version, the mechanical blockage of the flow in the *closed* state of the valve is replaced by a dynamic, inertial effect which is to be overcome by the fluid. This never suffices for stopping the flow completely. The rectification – conversion to one-directional movement – is therefore inherently less efficient than with the mechanofluidic counterparts. In microfluidics, there is a distinct continuing trend towards a smaller size and this – together with typically higher viscosity often pumped biological fluids – leads to lower Reynolds numbers. Since one of the interpretations of Reynolds number presents it as the ratio of inertial to viscous friction force acting on a fluid, this trend also contributes to the efficiency being generally indifferent or downright poor. This, however, is not of much significance in most microfluidic applications. The selling point of the "valve-less" pumps is their excellent suitability for micromanufacturing – no need for expensive assembly operations – long life, not endangered by breakage of springs or by moving components getting stuck, and suitability for operation at high working frequencies [1–3, 12].

Basic Methodology

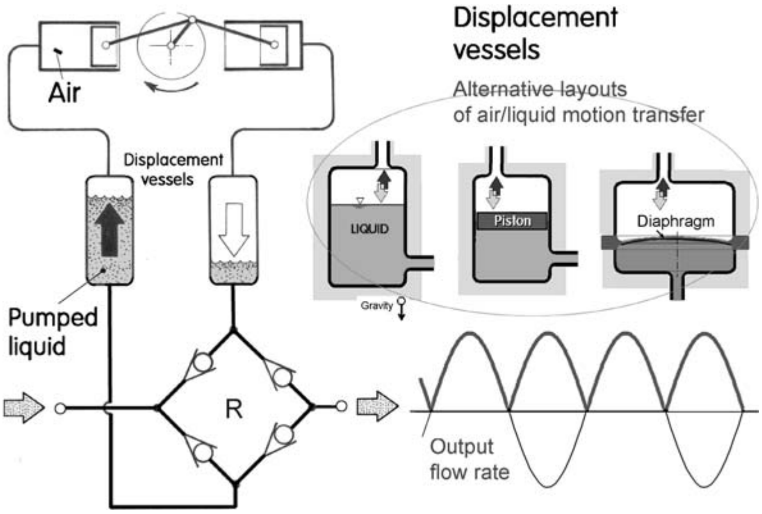
The Grätz Bridge Circuit

Usual present-day pumps in microfluidics are of the simplest configuration corresponding to Fig. 1. The actuator, represented in Fig. 1 symbolically by the traditional crankshaft-connecting rod-piston mechanism, generates the alternating flow, rectified by two one-way valves. During the first half of the cycle, the liquid is sucked into the displacement cavity through the upstream or suction valve. No fluid comes back into the cavity from the output, because the return flow is prevented by the upstream or delivery valve, which is oriented so that in this phase of the cycle it is in its *closed* state. Its state changes into the *open* in the subsequent half of the cycle when it allows the liquid, displaced by the actuator, to flow to the output terminal. Obviously, the output flow is intermittent, available only during one half of each operating period. The output flow pulsation is an obvious disadvantage.

In applications where the pulsation can cause problems – and also in those aiming at a higher efficiency – it is advisable to use, according to Fig. 2, the full-wave, Grätz bridge rectifier. Its name is explained in Fig. 3. It needs to be supplied by two-phase alternating input flow, carried in two channels. Generating it is usually no problem since the to-and-fro motion of the front side of the mechanical actuator



Valve-Less Rectification Pumps, Figure 1 Schematic representation of a single-action reciprocating pump. The alternating flow, shown symbolically as generated by a piston and crankshaft mechanism, is rectified by two fluidic diode valves. Their schematic symbol is derived from one of the oldest rectifying valve versions with a moving ball



Valve-Less Rectification Pumps, Figure 2 Schematic representation of the double-acting two-phase reciprocating pump. Two alternating flows, mutually shifted by π radians, are rectified by four fluidic diodes connected into the Grätz full-wave bridge. Also shown is one of the advantages of energy transfer by the alternating flow: the possibility of using different fluids (here gas and liquid) in different parts of the fluidic system

(symbolized in the drawing by the piston) means availability of a motion of the same amplitude with the opposite phase on its reverse side. The second phase may be also used differently, according to Fig. 4, to increase the generated output pressure. This is welcome in situations where the pump has to drive a high-dissipance load.

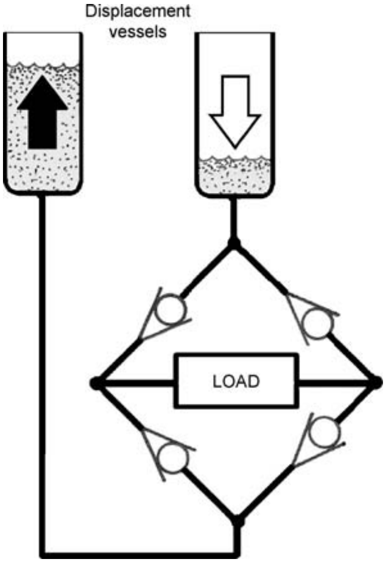
In the "valve-less" pumps, the mechanofluidic one-way valves are replaced by fluidic diodes. A diode is a device exhibiting different hydrodynamic properties for different directions of the flow. The effect is characterized by diodity – the ratio of dissipances

$$\boldsymbol{D} = \frac{Q_{\text{return}}}{Q_{\text{forward}}}, \tag{1}$$

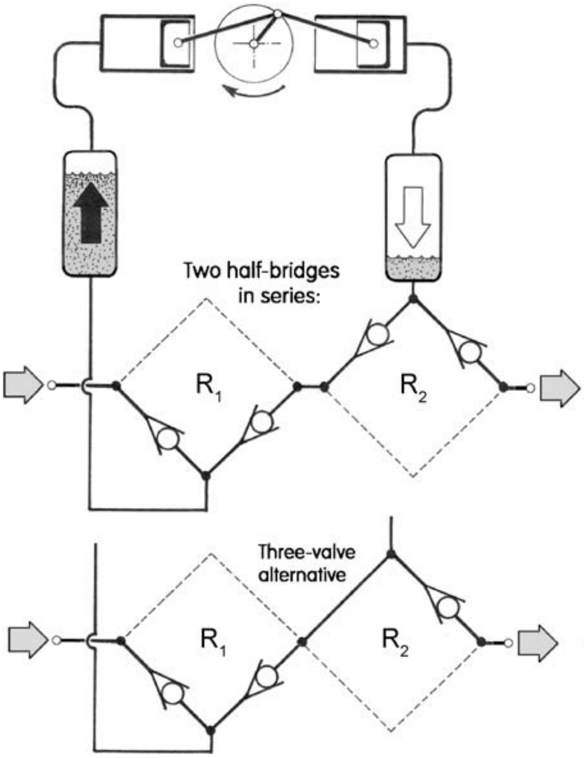
in the return and forwards flow directions. Diodity is usually evaluated in steady regimes, where it is generally found to increase with Reynolds number

$$\text{Re} = \frac{wd}{\boldsymbol{\nu}}, \tag{2}$$

where w [m/s] is the characteristic velocity, d [m] the characteristic length dimension of the device and $\boldsymbol{\nu}$ [m^2/s] is fluid viscosity. In unsteady regimes, the relation between the inertial and friction forces is different. The former increase in importance with increasing operating frequency f [Hz] of the alternating input flow. This is characteristically chosen higher as the size of the pump



Valve-Less Rectification Pumps, Figure 3 The reason why the Grätz circuit is called a "bridge": the load with one-way fluid flow is bridging the gap between the two parallel systems of diodes



Valve-Less Rectification Pumps, Figure 4 The double-acting, two-phase driving does not necessarily mean the use of the Grätz full-wave bridge. As shown here, the two phases may be used in half-bridges connected in series. The pulsation of the output flow is not suppressed, but the rectifier generates a higher output pressure

decreases. Rather than Reynolds number, the proper characterization criterion in these cases is the Stokes number

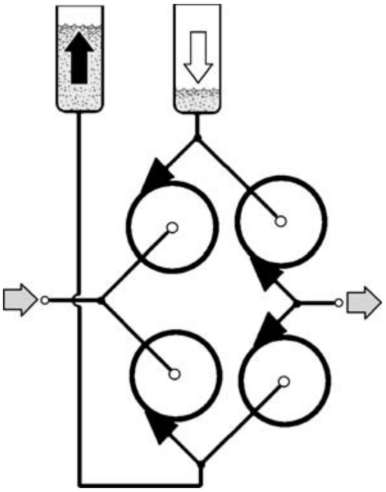
$$\mathrm{Sk} = \frac{f\,d^2}{\nu}\,. \tag{3}$$

Of the two-terminal fluidic diodes, the highest rectifying effect is offered by ▶vortex diodes (Figs. 5 and 6). In the *return* flow direction, the flow is opposed by the centrifugal action of rotation in the vortex chamber. The rectification is due to there being essentially no rotation with the central fluid entry into the vortex chamber in the *forward* flow regime. Diodity values as high as about $\boldsymbol{D} = 20$ have been achieved – not, however, with the simple version shown in Fig. 6. This can achieve, depending on its geometry, usually values of about $\boldsymbol{D} = 4$. The versions developed for really high performance are of more complex design, typically with a large number of inlets on the periphery of the vortex chamber, necessary for symmetry of the vortex motion. The inlets and the outlets have to be carefully shaped, the latter as diffusers. Use of vortex diodes in microfluidic pumps is limited by two factors. First, considering the structure of the full-wave bridge in Fig. 5, it is obvious that it is difficult or even impossible to accommodate into the typical planar configuration on a substrate plate the exits leading at right angles from the vortex chamber. Even more problems arise with the complex structure of the inlets in the high-performance versions. The second factor is the relatively poor frequency range. It takes a relatively long time to start up the rotation after the onset of the reverse *closed* state. This counters the modern trend towards operation at a high frequency with small-volume displacement cavities.

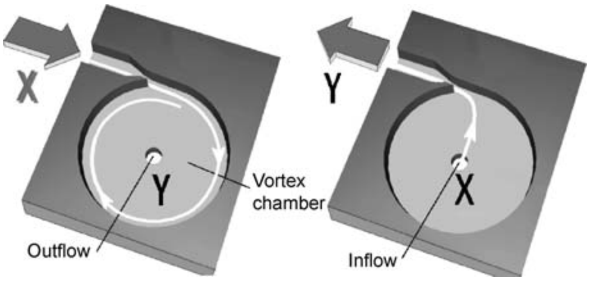
More suitable for microfabrication, because of their planar layout, are the Tesla diode (Fig. 7) and the various versions of the labyrinth diodes, in particular the one shown in Fig. 9. Experience with the former type, patented in 1920 by the inventor N. Tesla, has been unfortunately somewhat disappointing. An improved version, the Tesser valve, is described in [4]. To improve the effective overall diodity, these devices are usually designed in multi-stage arrangements – the downstream stages in the Tesla diode actually benefiting from the jet-deflection phenomenon of the stage located upstream. The diodity $\boldsymbol{D}$ is, however, rarely larger than 1.2 to 1.6.

Better performance and, because of the short and simple path, high-frequency range are characteristic of the ▶venturi diode, consisting of a nozzle and a diffuser placed in series. Under various other names [5], it is currently among the most popular among the no-moving-part rectifiers (Figs. 10 and 11). An application of the use of a two-Venturi rectifier circuit in a flow control actuator for gen-

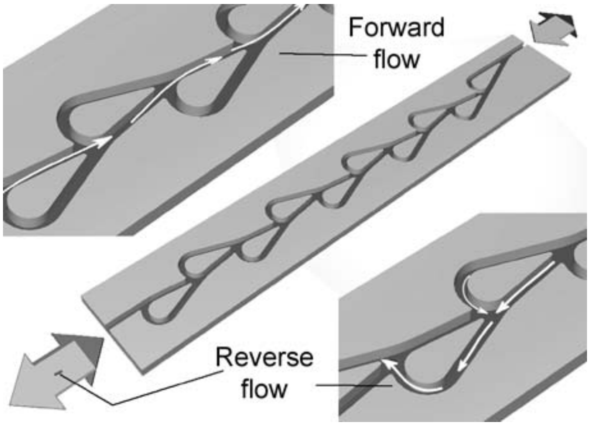
V



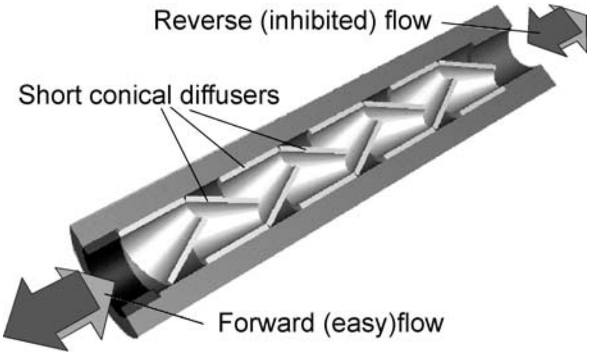
Valve-Less Rectification Pumps, Figure 5 Rectification by vortex diodes – in the double-acting two-phase Grätz full-wave bridge. The advantage is the absence of the moving parts; disadvantages are the slow start-up of diodes and necessity of complex spatial layout



Valve-Less Rectification Pumps, Figure 6 A simple version of the vortex diode. At left is the *closed* state with rotation in the vortex chamber; at right is the easy flow, *open* state with radial forward flow. High-performance diodes have several tangential inlets into the chamber, resulting in symmetric character of the flow – but lead to an even more difficult spatial layout of the rectifier circuit



Valve-Less Rectification Pumps, Figure 7 The Tesla diode, one of the earliest no-moving-part devices. As shown here, it is usually used in a multi-stage layout. Diodity is very much worse than with vortex diodes

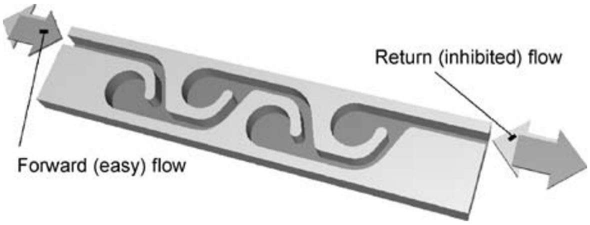


Valve-Less Rectification Pumps, Figure 8 A typical example of the labyrinth diode, here built using short conical tubes

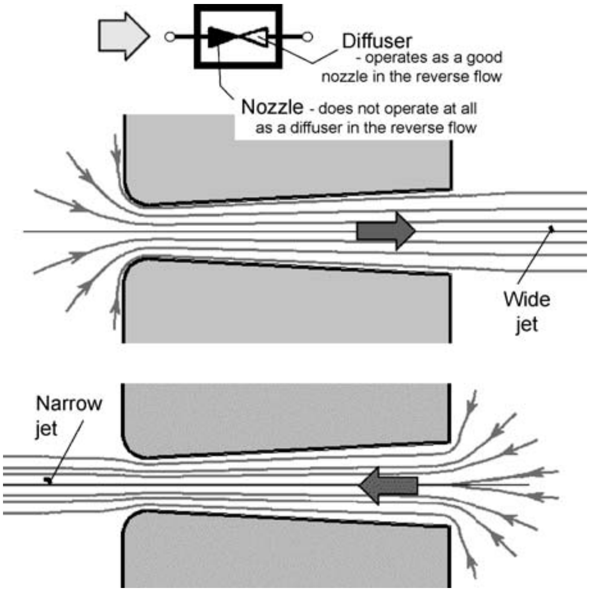
eration of hybrid synthetic jets [6] is an example of a use of the rectifier circuits other than in simple pumps.

Jet-Type Rectifiers

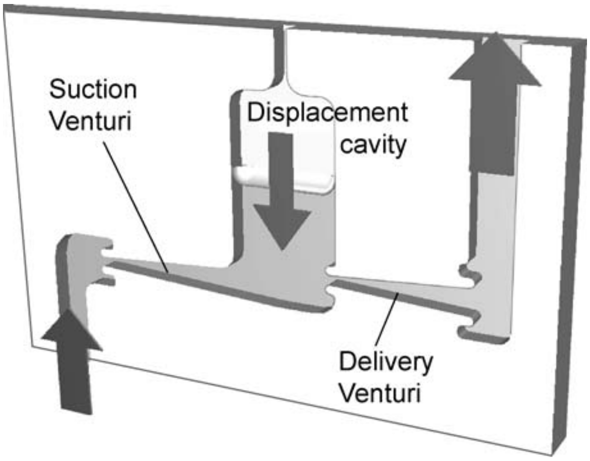
Rectification based on properties of a fluid jet is a very old technique but used to be mostly applied in devices of little importance, such as aquarium ventilators, coolers or humidifiers, where the dominant requirement was low cost. Sometimes the decisive factor for their use was the fact that inertia of moving parts in mechanofluidic diodes prevents them from operation at the frequency of AC mains (also wear of contacting moving components would be too rapid at this frequency). Typically, descriptions in the literature are missing as the designers (and usually inventors) did not consider the solution of this peripheral problem in the main pumping design task worthy of publication. Probably the first reference in the literature is from 1957, when Dauphinne described in a short note the use of the *loudspeaker wind* for a simple closed-circuit cooling. He used a standard loudspeaker provided with a front plate having a central orifice forming a simple displacement vessel with a nozzle. The flow generated and used for cooling would nowadays be called the *synthetic jet*. Better documented use of the jet-type rectifier – in a pump for moving molten salts – was described by Walkden and co-workers (e. g. [7]). Their rectifier was developed from a standard jet pump (Fig. 12a). A very similar jet-pump rectifier was later tested by the present author [8]. To obtain the full-wave rectification, Walkden provided the jet pump with two primary nozzles in parallel, each supplied with one phase of the alternating two-phase flow. An even more important improvement was replacing the two nozzles by diffusers (Fig. 12b). This led to better efficiency



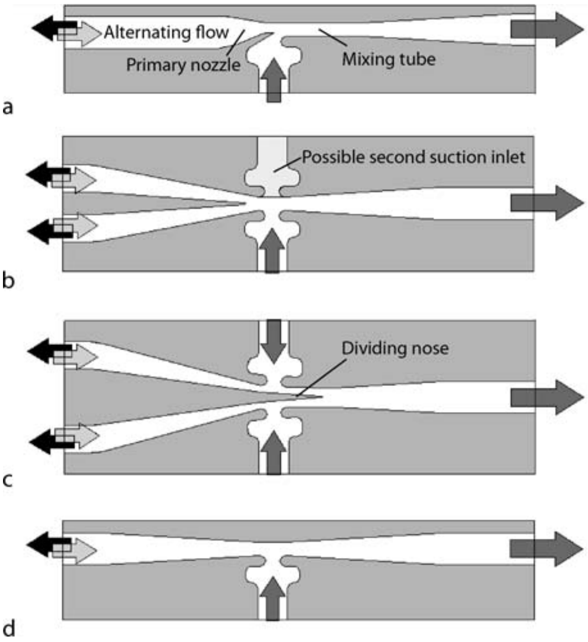
Valve-Less Rectification Pumps, Figure 9 Planar labyrinth diode, more suitable for micromanufacturing: again a multi-stage version



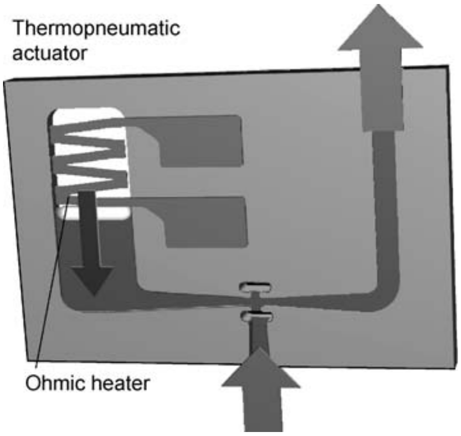
Valve-Less Rectification Pumps, Figure 10 Rectification effect in the Venturi (convergent–divergent) diode is based on the larger energetic loss by dissipating kinetic energy of the narrower jet



Valve-Less Rectification Pumps, Figure 11 Single-action pump with the Venturi diode rectifier. This is currently the most common type of "valve-less" pumps used in microfluidics

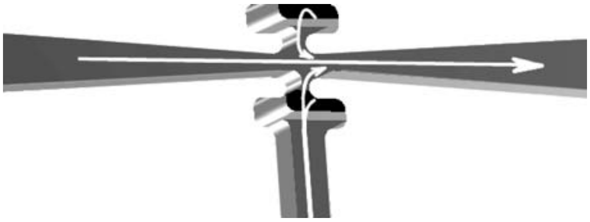


Valve-Less Rectification Pumps, Figure 12 Survey of the jet-type diodes. (**a**) A standard jet pump may exhibit a reasonable rectification effect. (**b**) The Walkden two-phase full-wave rectifier was developed from a jet pump with two parallel "primary nozzles", actually better performing when shaped as diffusers. (**c**) Tippetts' analysis of the long-nosed symmetric Walkden rectifier found it actually consists of three three-terminal devices. (**d**) The three-terminal Venturi, sometimes known as RFD device

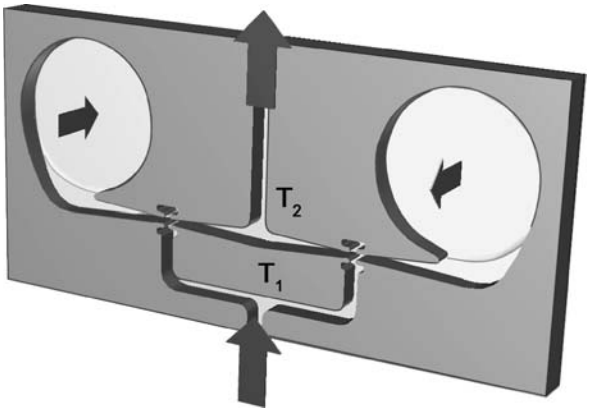


Valve-Less Rectification Pumps, Figure 13 A simple single-action pump with the three-terminal Venturi rectifier. Less known than the version from Fig. 11, it can exhibit higher rectification efficiency. The alternating flow is generated by expansion of gas heated electrically by the resistance heater

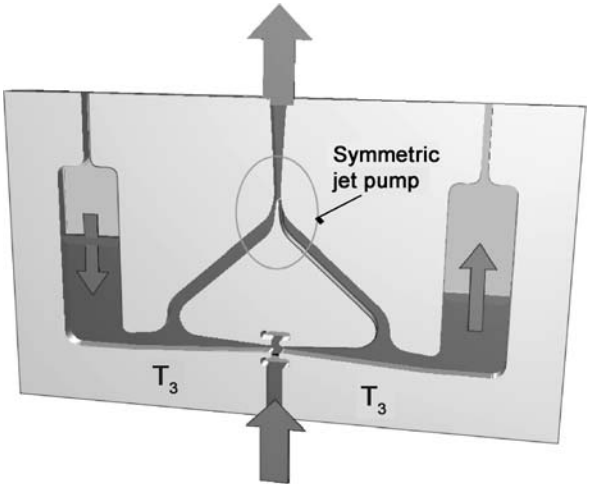
V



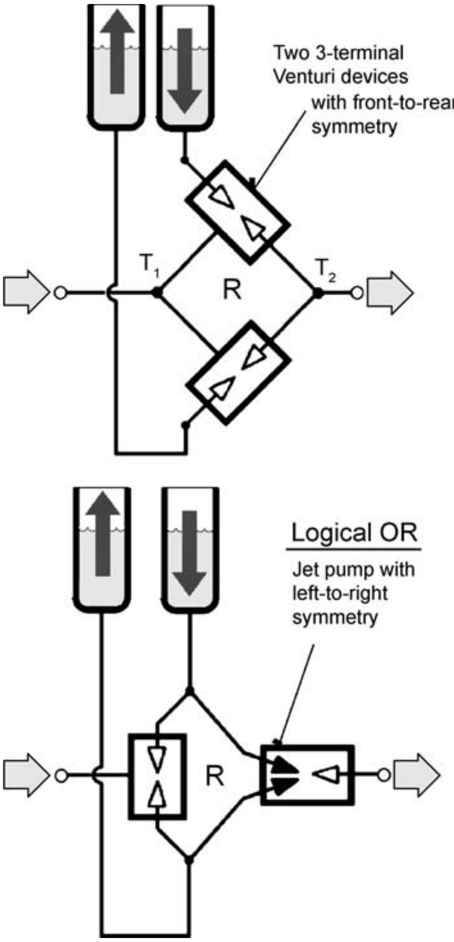
Valve-Less Rectification Pumps, Figure 14 Operation of the three-terminal Venturi rectifier. Fluid from the suction pipe of the pump enters the rectifier due to the jet-pumping effect of entrainment into the jet, which appears in both flow halves of the operating cycle



Valve-Less Rectification Pumps, Figure 15 The double-action full-wave pump with two three-terminal Venturi rectifiers. Alternating flow is generated by deformation of round diaphragms



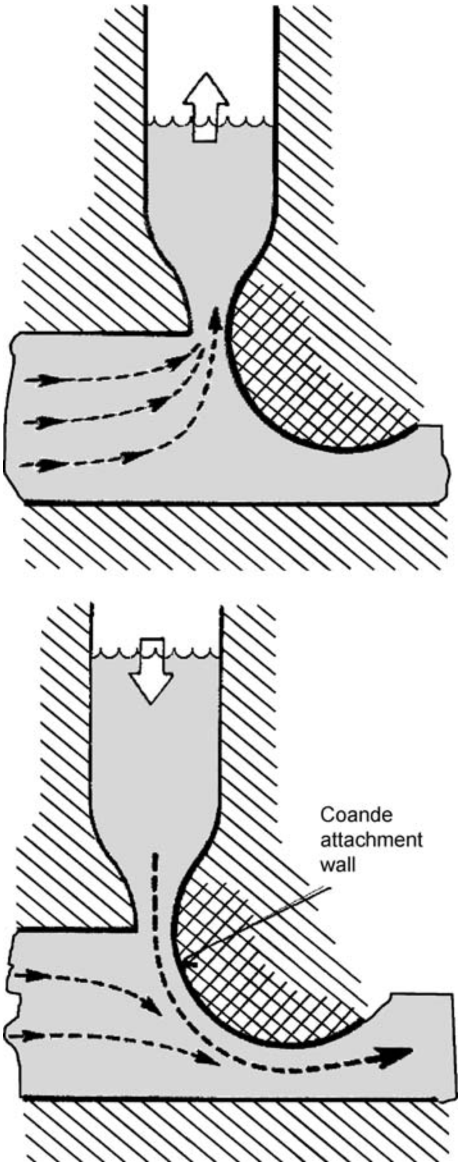
Valve-Less Rectification Pumps, Figure 16 The Tippetts version of the double-action pump with the single three-terminal Venturi rectifier and a symmetric jet pump in the opposite vertex of the Grätz bridge



Valve-Less Rectification Pumps, Figure 17 Schematic fluidic circuit diagrams of the two pumps from Fig. 15 (left) and Fig. 16 (right)

due to the absence of flow separation from the walls in the reverse flow direction. Analysis of the Walkden rectifiers led Tippetts [9] to discovering the importance of the three-terminal device shown in Fig. 12d as a member of version C of the variant of Walkden's rectifier shown in Fig. 12 – and the proposal (also in [9]) to use this device alone in a reciprocating jet pump (Fig. 13). The return flow from the load during a part of the cycle was acknowledged as inevitable – and actually made use of by arranging the rectifier device (Fig. 14) so that the jets are formed in both flow directions and the pumped fluid is sucked in from the input inlet due to the entrainment effect of the jets.

Though also using the same two diffusers as the now standard design of Fig. 11, the pump according to Fig. 13, less well known, has more effective rectification. Tippetts himself went on later to extend this principle to the full-wave two-phase operation. He did not follow the more obvious additive layout of Fig. 15, presented also schematically in the left half of Fig. 17. Instead, he placed the rectifier devices into the other vertices of the Grätz bridge, where

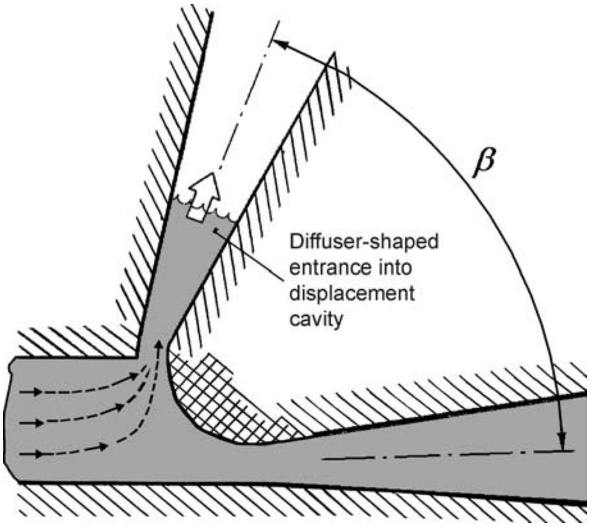


Valve-Less Rectification Pumps, Figure 18 Operating principle of the jet-type rectifier with the *forward flow diverting* by the Coanda effect. The original version with a nozzle at the inlet into the displacement cavity [10]

the single direction of the output flow made possible the replacement of the upstream three-terminal device by the symmetric jet-pump OR logical element.

Traveling Wave Pump

Essentially also a jet-type rectification, this is an alternative that features several important improvements [11]. One of them is the use of the Coanda effect attachment to a curved wall. This wall is positioned so that it turns the direction of the forward flow coming from the dis-



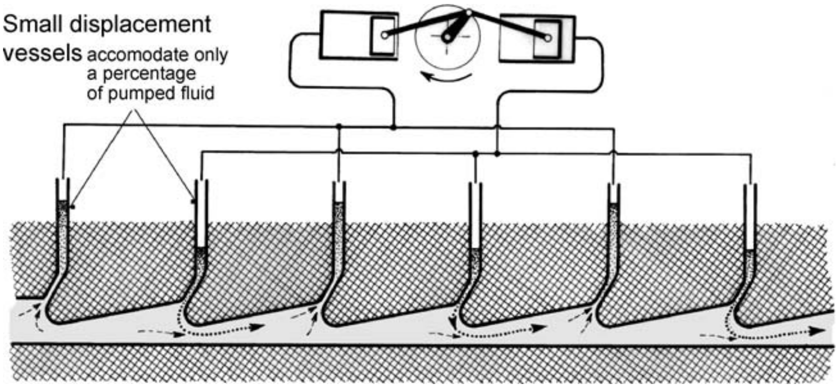
Valve-Less Rectification Pumps, Figure 19 Later improvement of the principle from Fig. 18. Energetic loss associated with inflow into the displacement cavity is reduced by the inlet being shaped as a diffuser. The small angle β (compared with the full 80°in Fig. 14) is made possible by the change of the jet direction due to the Coanda effect attachment to the curved wall

placement cavity. The general direction of the main flow through this rectifier is straight and a considerable proportion of the pumped liquid actually continues in the straight direction without ever entering the displacement cavity. A recently tested version (Fig. 22) uses the principle from Fig. 18, with a number of displacement cavities arranged along the channel length. The entrances into the cavities are placed at a streamwise pitch which corresponds to the distance traveled from one displacement cavity to the following one by the attached Coanda jet during one half of the period. As a result of this timing, the outflows from the cavities form a traveling wave passing through the channel. With proper adjustment of operating frequency it is possible to enter the resonant regime in which the efficiency reaches very high values. Little has been done so far with the improved version of Fig. 19, with angular position of the inlets into the displacement cavities ($\beta < \pi$; in fact $\beta < \frac{\pi}{2}$ (Fig. 19) decreasing the hydraulic losses associated with flow direction change.

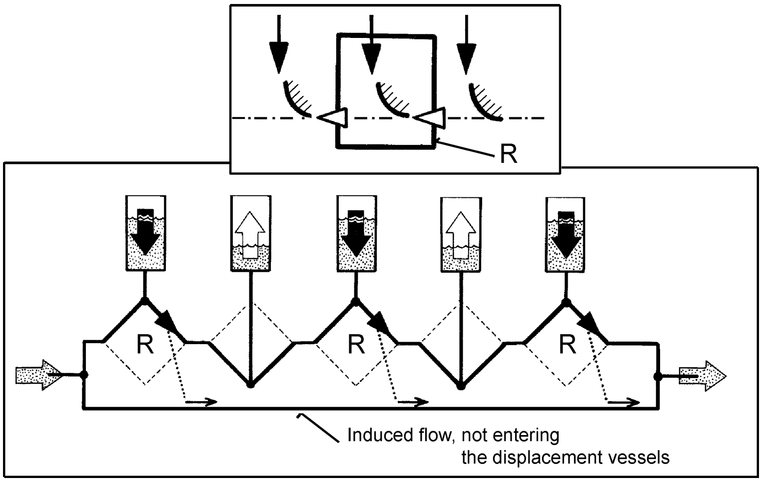
Other Principles

To round off the list, the peristaltic pumps should be mentioned. They use a multi-phase multi-stage arrangement similar to that of Fig. 20, but in their common form they are based on much less effective rectification elements.

Finally, a useful rectification has been also demonstrated based on temperature dependence of viscosity. Ohmic



Valve-Less Rectification Pumps, Figure 20 The principle of the traveling-wave pump, two-phase, three-stage rectifier based on the principle from Fig. 19. A substantial proportion of the pumped liquid does not enter the displacement cavities – instead, it is dragged along with the wave



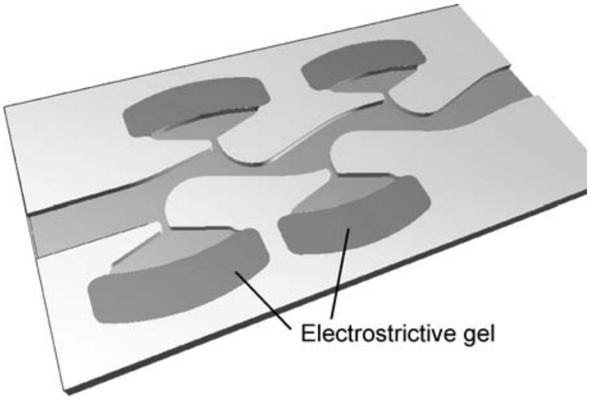
Valve-Less Rectification Pumps, Figure 21 Schematic representation of the working principle (above) and the relation to the Grätz half-bridge principle

heating of the delivery channels synchronized with the flow from the displacement cavity is used with liquids which decrease their viscosity in response to the heating. In a similar design, the electric heating of the liquid is so intense that it leads to boiling – generation of bubbles in the channel resisting the flow by surface tension.

Key Research Findings

Existing designs of microfluidic pumps with operation based on valve-less rectification demonstrate the practical applicability of no-moving-part flow generation and control principles [12]. The absence of moving components makes these pumps attractive for applications stressing the aspects of high reliability, long life and absence of any maintenance. They are also more suitable for micromanufacturing techniques, such as etching, than the pumps with return flow control by mechanical moving components. On the other hand, without the moving components the return flow in the valves is never suppressed completely. As a result, the valve-less pumps are considerably less efficient and therefore suitable for those applications where efficiency of pumping is not of primary importance.

Since the suppression of the return flow in the valve-less pump is based on inertial effects in flowing pumped fluid, the efficiency of the pump decreases with decreasing Reynolds number. This is a serious factor, since the general trend of operating at progressively smaller Reynolds numbers is typical for modern microfluidics [12]. To oppose this effect, it is found useful to employ in a microfluidic system with several circuits, a central pump for driving the flow in all these circuits rather than distributed driving by a separate pump in each circuit. For the central pump, this means a larger size and larger handled flow rates so that the Reynolds number is not so low.



Valve-Less Rectification Pumps, Figure 22 An example of a micropump using the principle from Fig. 18 and generation of the flow wave by alternative suction into the nozzles on both sides of the channel. Nozzles belonging to on phase are on the same side of the channel. Alternating flow is generated by displacement due to volume of a liquid crystal gel exposed to an electrostatic field

Future Directions for Research

The use of the attractive properties of valve-less pumps being limited by the generally poor efficiency, further development concentrates on research aimed at obtaining a higher efficiency of the rectification, especially at low Reynolds number flows. Besides development of new rectification principles with better properties, higher efficiency is obtainable by operating at a higher frequency and therefore higher values of the Stokes number (Eq. (3)). However, this way towards a better performance is not applicable for all operating principles; it is not suitable for those flow mechanisms characterized by long flow paths. From this point of view, it seems advisable to direct future research to the jet-type rectification principles.

Velocimetry

Synonyms

Flow profiling

Definition

Velocimetry is the measurement of fluid velocity. In the context of microfluidics and nanofluidics, velocimetry involves the determination of the velocity field in small scale internal flows. Most commonly, velocimetry involves optical tracking of a fluid marker. In such cases the terms flow visualization and velocimetry are used interchangeably. A variety of velocimetry methods have been developed for small scale flows. Visualization based methods can be divided into particle-based techniques, such as micro-particle image velocimetry, and scalar-based techniques, such as molecular tagging. Non-visualization based velocimetry methods have also been developed, such as electrochemical velocimetry where fluid velocity is determined via generation of a redox species.

Flow sensors; Flow meters

Definition

Flow velocity in microchannels can be measured by means of flow sensors. The basic principle of measuring flow velocity is by monitoring the flight time of particles or elements in the moving fluid after heat impulses are injected. The time taken for the particles or elements to move between two predetermined points is called the flight time. In addition, some principles in heat transfer and fluid dynamics are also applied to give precise estimation of flow conditions. Flow velocity is obtainable from flow rate. The flight time unit is second (s), the flow velocity unit is micrometer per second (μm/s) and the flow rate unit is microliter per minute (μl/min). The units for flow velocity and flow rate can sometimes be of nano- and picoscale order of magnitude.

Overview

Fluid (gas, liquid) systems such as natural gas supply or water supply use flow meters, the devices that can be used to estimate the amount of fluid supplied. They are also found in automotive applications in engine control and emission and in fuel flow and consumption, and in biomedical instrumentation [1]. A trend over the last decade has been to develop biochemical sensors that are very small in size. Typical measuring parameters are the temperature, the electrolyte conductivity, the flow rate, the liquid level and the concentration of ions, gases and enzymes. Among these sensors are the flow sensors, the devices that detect physical quantities of fluid flow such as the flow velocity. It was then expected that there were potential applications of these sensors for microanalysis technologies and systems that include analytical chemistry, biotechnology, medicine, environment monitoring, space investigations and industrial process control [2].
A miniature fluid system usually handles transportation of fluids filled with particles and/or biomacromolecules such as protein solution or cell lysate. This system, also called a microfluidic system, works with a flow rate of the order

Velocity Sensors, Table 1 Notations and symbols

Notation	Symbol	Notation	Symbol	Notation	Symbol
Coordinates	x, y, z	Density	ρ	Kinematic viscosity	υ
Velocity components	u, v, w	Stress	τ	Reynolds number	Re

Nusselt number	Nu	Heat transfer coefficient	α, h	Power	P
Thermal conductivity coefficient	λ, k	Specific heat coefficient	c_p	Volume	V
Temperature	T	Heat conductance	G	Incoming fluid temperature	T_∞

of pl/s to nl/s and where its microchannels have diameters less that a millimeter. Due to the small flow rate required by the system, it depends on micropumping to provide the fluid flow. A micropump, a device that produces a small-scale fluid flow, uses electrical or mechanical stimulus to drive the flow [3]. An example of a pump used in micropumping is the syringe pump. Current trends are to develop microfluidic systems for precise control of gas and liquid flows. The designs typically consist of integrated microfluidic components such as pumps, valves and sensors [4].

Basic Methodology

In this section, the fundamental principles of fluid flow and heat transfer are introduced. Additionally, two representative approaches in flow velocity measurement using pulse modality flow sensors and calorimetric-type gas flow sensors are discussed. There are a number of notations found in the text: Table 1 lists the notations and their respective symbols. Moreover, the articles found in the cross-references list are useful for further understanding of the topics discussed here.

Fluid Flow

In the early 1800s the Navier–Stokes equations were independently derived by G. G. Stokes and M. Navier [5]. These are a set of equations that describe the motion of a fluid. It consists of a time-dependent continuity equation for conservation of mass, three time-dependent conservation of momentum equations and a time-dependent conservation of energy equation. The flow condition can be estimated using these equations.
The continuity equation for conservation of mass where the amount of mass remains constant is

$$\frac{\partial \rho}{\partial t} + \frac{\partial(\rho u)}{\partial x} + \frac{\partial(\rho v)}{\partial y} + \frac{\partial(\rho w)}{\partial z} = 0 \tag{1}$$

The following equations give the x, y, z momentums for conservation of momentums respectively where the amount of momentum remains constant:

$$\frac{\partial(\rho u)}{\partial t} + \frac{\partial\left(\rho u^2\right)}{\partial x} + \frac{\partial(\rho uv)}{\partial y} + \frac{\partial(\rho uw)}{\partial z} = -\frac{\partial \rho}{\partial x} + \frac{1}{\mathrm{Re}}\left(\frac{\partial \tau_{xx}}{\partial x} + \frac{\partial \tau_{xy}}{\partial y} + \frac{\partial \tau_{xz}}{\partial z}\right) \tag{2}$$

$$\frac{\partial(\rho v)}{\partial t} + \frac{\partial(\rho uv)}{\partial x} + \frac{\partial\left(\rho v^2\right)}{\partial y} + \frac{\partial(\rho vw)}{\partial z} = -\frac{\partial \rho}{\partial y} + \frac{1}{\mathrm{Re}}\left(\frac{\partial \tau_{xy}}{\partial x} + \frac{\partial \tau_{yy}}{\partial y} + \frac{\partial \tau_{yz}}{\partial z}\right) \tag{3}$$

$$\frac{\partial(\rho w)}{\partial t} + \frac{\partial(\rho uw)}{\partial x} + \frac{\partial(\rho vw)}{\partial y} + \frac{\partial\left(\rho w^2\right)}{\partial z} = -\frac{\partial \rho}{\partial z} + \frac{1}{\mathrm{Re}}\left(\frac{\partial \tau_{xz}}{\partial x} + \frac{\partial \tau_{yz}}{\partial y} + \frac{\partial \tau_{zz}}{\partial z}\right) \tag{4}$$

The energy equation where the amount of energy remains constant is

$$\begin{aligned}\frac{\partial(E_T)}{\partial t} &+ \frac{\partial(uE_T)}{\partial x} + \frac{\partial(vE_T)}{\partial y} + \frac{\partial(wE_T)}{\partial z} \\ &= -\frac{\partial(up)}{\partial x} - \frac{\partial(vp)}{\partial y} - \frac{\partial(wp)}{\partial z} \\ &- \frac{1}{\mathrm{Re\,Pr}}\left(\frac{\partial q_x}{\partial x} + \frac{\partial q_y}{\partial y} + \frac{\partial q_z}{\partial z}\right) \\ &+ \frac{1}{\mathrm{Re}}\left(\frac{\partial}{\partial x}\left(u\tau_{xx} + v\tau_{xy} + w\tau_{xz}\right)\right. \\ &+ \frac{\partial}{\partial y}\left(u\tau_{xy} + v\tau_{yy} + w\tau_{yz}\right) \\ &\left.+ \frac{\partial}{\partial z}\left(u\tau_{xz} + v\tau_{yz} + w\tau_{zz}\right)\right)\end{aligned} \tag{5}$$

Heat Transfer

The passage of thermal energy from a hot to a cold body is called heat transfer in thermal physics. It can occur through conduction, transfer of heat through matter; convection, transfer of heat through moving liquids and gases; and radiation, transfer of heat through electromagnetic radiation emitted from the surface of an object which is due to the object's temperature [6]. However, radiation heat transfer usage in microfluidic flow sensors has not been found. In 1822, Joseph Fourier proposed a conduction process as in Eq. (6); in 1701, Isaac Newton suggested a convective process as in Eq. (7):

$$q = -k\frac{\mathrm{d}T}{\mathrm{d}x} \tag{6}$$

$$q = \bar{h}\left(T_{\mathrm{body}} - T_{\infty}\right) \tag{7}$$

Representative Approaches in Flow Velocity Measurement

The sensor output signal of pulse modality flow sensors is strongly tied to the relationship between sensing element temperature and flow rate as well to the relationship between sensing element resistivity and temperature [7]. Further explanation of its functionality is discussed in the next section. In steady state, the input heat transfer is balanced by power dissipation:

$$P = Q_{\mathrm{conduction}} + Q_{\mathrm{convection}} \tag{8}$$

The amount of heat transferred to the fluid is proportional to the temperature difference between the hot sensing element and the fluid temperature:

$$Q_{\mathrm{convection}} = G_{\mathrm{convection}}\left(T_{\mathrm{s}} - T_{\mathrm{f}}\right) \tag{9}$$

Equation (10) is the surface heat flux per unit area. Considering laminar flow and the decreasing thermal boundary layer with increasing velocity, the heat transfer increases in relation with the flow velocity.

$$Q'_{\mathrm{convection}} = 0.332\lambda\left(T_{\mathrm{s}} - T_{\mathrm{f}}\right)\left(\sqrt[3]{\mathrm{Pr}}\right)\sqrt{\frac{v}{x\upsilon}} \tag{10}$$

Calorimetric-type gas flow sensors analyze the temperature distribution built up in the environment around a central heater element [2]. Further explanation of its functionality is discussed in the next section. Using thermal electric circuits, thermal behavior of the sensor's structure is determined. A number of resistors and capacitors are used in the circuit to function as heat transfer agents. Equation (11) is modeled for convective resistance, and Eq. (12) for thermal capacitance where A is the heater area. The flow velocity can be obtained from Eq. (12).

$$R_{\mathrm{convection}} = \frac{1}{\alpha A} \tag{11}$$

$$R_{\mathrm{capacitance}} = \frac{1}{\rho c_{\mathrm{p}} A v} \tag{12}$$

Key Research Findings

In this section, the operating principles of selected gas velocity sensors and liquid velocity sensors are explained.

Gas Velocity Sensors

Calorimetric Sensors. The calorimetric type of gas flow sensors analyze the temperature distribution built up in the environment around a central heater element [2]. A photograph of a novel calorimetric sensor design is shown in Fig. 1, while Fig. 2 depicts the general idea behind the concept of calorimetric-type gas flow sensors. Figure 2 shows a single channel with two sensing elements, the temperature resistors, attached upstream and downstream of the direction of flow. These elements confirm the direction of flow that can be in two possible directions.

In between the elements is the central heater that heats up the gas as it passes by. This arrangement allows gas velocity to be measured. The thermal conduction, convection and laminar flow condition of the gas are used for gas velocity determination. Figure 3 shows a typical output of this sensor. It depicts the simulated temperature values of the upstream and downstream resistors for different heater temperatures using nitrogen gas. It can be seen that the temperature difference between the upstream and downstream resistors increases with the flow velocity. The sensor is said to be useful in measuring explosive gas mixture concentrations.

C-MOS Compatible Silicon Gas Flow Sensors. The top view of a novel C-MOS compatible silicon gas flow sensor is exhibited in Fig. 4. The dimension (D) is the width of the porous silicon isolation area. Its function is to measure gas flow velocity applying the principle of heat transfer [1]. The sensor is fabricated using porous silicon. It consists of two thermopiles which have two series of aluminum/p-type polysilicon thermocouples. Thermocouples are types of temperature sensor that convert thermal potential difference into electric potential difference [8].

The heater and the thermopiles are placed on a thick porous silicon layer. There are numbered pads on the top surface of the sensor. Input electric current is introduced to the heater through certain pads to generate heat. Another

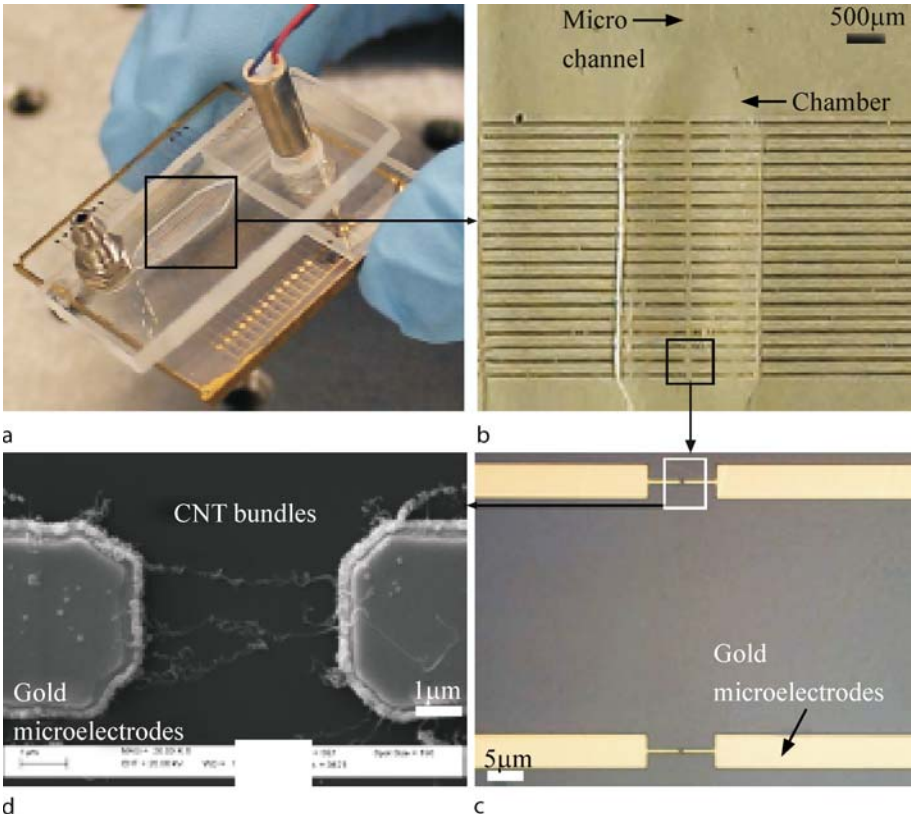
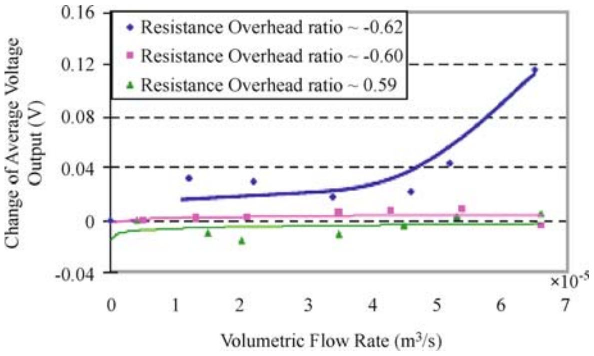
option is through pads that have compensation resistors whose characteristics resemble those of the heater. Figure 5 shows the sensor's typical output. It describes the thermopiles' output voltage difference as a function of gas flow velocity. This output is a result of an experiment where nitrogen gas flow in the range of 0 to 1000 standard cubic centimeters per minute at room temperature was introduced.

Carbon Nanotube (CNT)-based Microelectromechanical Systems (MEMS) Flow Sensors. CNT-based MEMS flow sensors can be used to detect air flow inside a poly(methyl methacrylate) (PMMA) microfluidic chamber [9]. Figure 6 shows the sensor's system prototype. The system applies the principle of heat transfer by electrical current heating, flow resistance dependency and current–voltage characteristics to measure gas flow velocities.



Velocity Sensors, Figure 6 (**a**) Photograph of a flow sensor chip with multi-walled carbon nanotube (MWNT) sensing element; (**b**) optical microscope image showing an array of MWNT sensors inside a PMMA chamber; (**c**) optical microscope image showing two pairs of microelectrodes with CNT bundles; (**d**) scanning electron microscope image showing the formation of MWNTs (~ 5 μm in length) between gold microelectrodes [9]

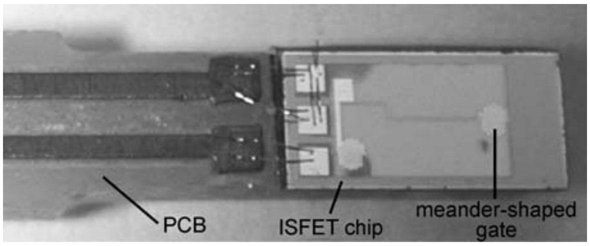
Figure 7 exhibits a typical result produced by the sensor. In this experiment, a constant current mode circuit is used to generate heat in the sensor with different overheat ratios. As a result, the thermal heat transfer mechanisms across the sensor affect the flow sensitivity. The air flow is supplied using a vortex micropump, a device that produces fluid flow in microliter and nanoliter volumes [8]. The sensor is claimed to have potential for biocompatible and low-cost sensing applications.



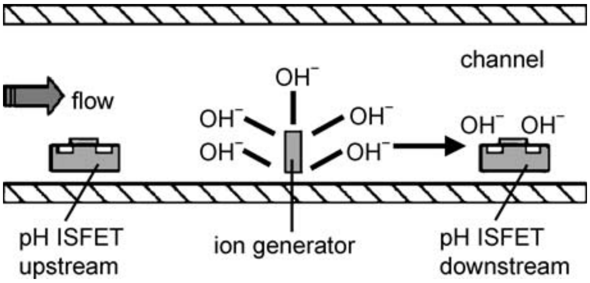
Velocity Sensors, Figure 7 Output voltage variations with different ait flow supplied by an air compressor. Three curves represent three different overheat ratios for the same sensor [9]

Liquid Velocity Sensors

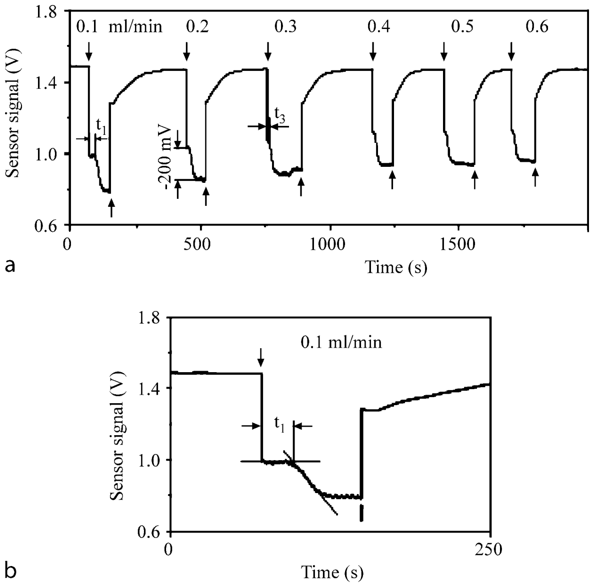
Ion-Sensitive Field-Effect Transistor (ISFET)-based Flow Velocity Sensor. The ISFET-based flow velocity sensor functions as a flow direction and diffusion coefficient detection device [10]. It senses the velocity of liquid through detection of ions. The sensor is shown in Fig. 8. It shows a chemical sensor-actuator system having one ion generator and one detector. The generator–detector pair detects ions that are electrochemically generated. Positive potential applied to the generator electrode results the electrochemical reaction in water solution generating hydrogen ions (H^+). Likewise, hydroxyl ions (OH^-) are generated when a negative potential is applied to the generator electrode. These ions are called the chemical tracers.



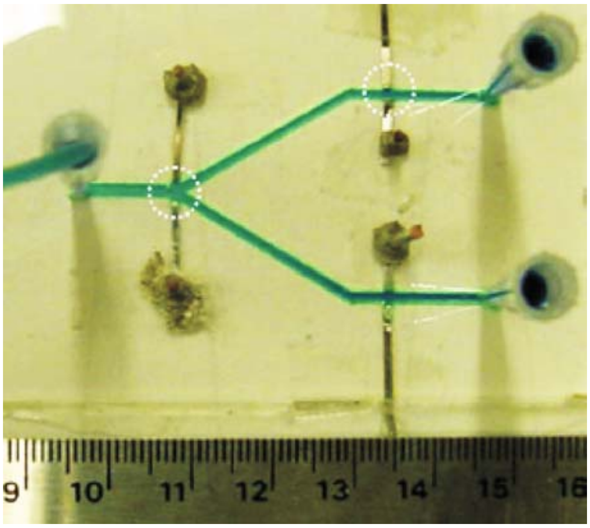
Velocity Sensors, Figure 8 Photograph of a flow sensor with a single ISFET placed onto a printed circuit board before encapsulation [10]



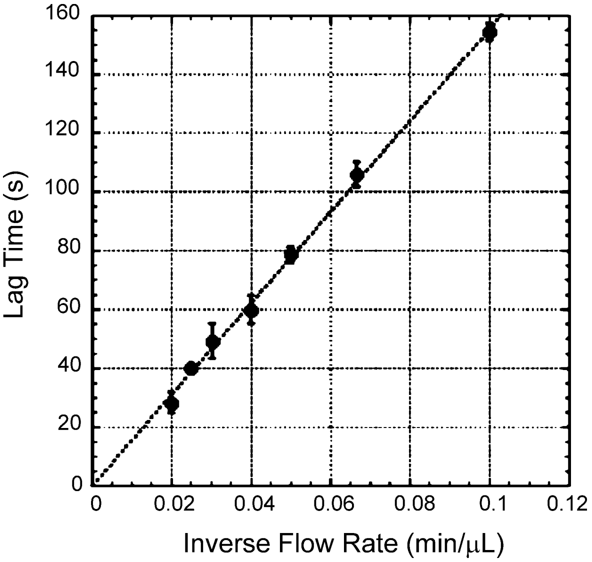
Velocity Sensors, Figure 9 Schematic of a sensor. The corresponding electrochemical reactions for H^+ and OH^- ion generation through the electrolysis of water solution are shown



Velocity Sensors, Figure 10 Typical output signal of an ISFET-based flow velocity sensor at different flow rates from 0.1 to 0.6 ml/min (**a**) and determination of the time of flight (**b**). In this experiment, OH^- ions were generated by a constant current of 30 μA to reach a constant sensor signal. The arrows mark the time of the beginning (arrows downwards) and the end of generation (arrows upwards). The time of flight (t_1) is that needed for the generated OH^- ions to reach the ISFET gate region [10]

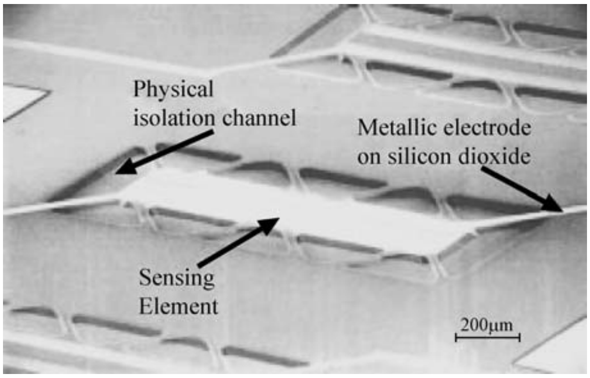


Velocity Sensors, Figure 11 Image of a milliscale prototype. The dotted circles show the separator (left) and analyzer (right) regions. The prototype was made with two analyzers, one on each arm, but only one was used at a time. Ruler scale is in centimeters [3]

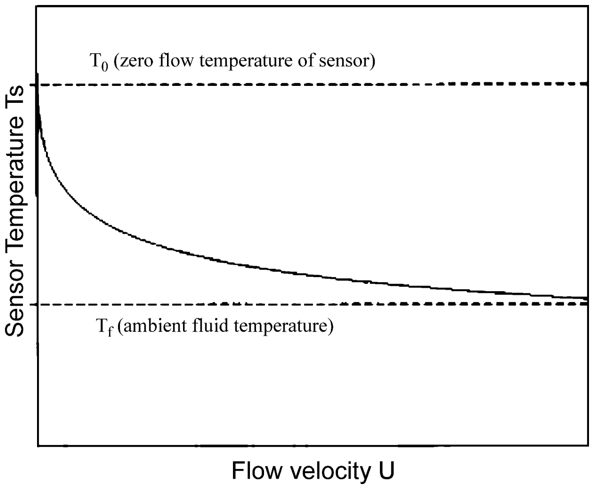


Velocity Sensors, Figure 12 Calibration of a LAPS meter. Lag time was calculated for bovine serum albumin solutions pumped at 10 – 50 μl/min. The lag time was found to be inversely proportional to the flow rate [3]

Figure 9 shows the flow of water solution passing by the ion generator. The ions generated here are then transported until they are detected upon reaching the downstream ISFET. Fluid velocity is measured by the time difference between detection and generation of the ions. The time difference is called the flight time and is inversely proportional to the mean velocity. Knowing the fluid velocity



Velocity Sensors, Figure 13 Scanning electron micrograph of the top of a linear array of three fabricated flow sensors [7]



Velocity Sensors, Figure 14 Theoretical sensor temperature T_S versus fluid (water) velocity U, beginning at temperature T_0 and asymptotically approaching final ambient temperature T_f [7]

given that the relevant dimensions of the channel are also known, the flow rate can be determined as well. ISFET is said to have a fast response so it can be used to measure flow velocity in an operating range of μm/s to m/s. Figure 10 exhibits a typical output signal of an ISFET-based flow velocity sensor. It explains how the time of flight is determined. This output is obtained from an experiment where a constant electrical current of 30 μA is applied that generates hydroxyl ions. The arrow that points downwards marks the beginning of the flight time; where it ends is marked by the arrow pointing upwards.

Lag-After-Pulse-Separation (LAPS) Meter. The LAPS meter is a flow meter that measures flow rates of suspensions laden with protein or other charged macromolecules or particles [3]. The sensor prototype is shown in Fig. 11. The sensor system has a channel that branches into two subchannels. The subchannels merge again to allow the flow to continue. There is a pair of electrodes attached at the main channel (as shown in the left dotted circle in Fig. 11) called the separator. When the separator is not supplied with direct-current voltage the particles will move with the fluid. This produces a uniform flow in the main channel as well as in the two subchannels. However, when a finite-duration pulse of direct-current voltage is applied to the separator, the fluid with particles is forced to flow towards one of the subchannels.

There is also a pair of electrodes attached at each subchannels (as shown in the right dotted circle in Fig. 11) called the analyzer. The time taken for the pulse traveling downstream to reach the analyzer location is related to the inverse of the flow rates. The analyzer monitors particle concentration by measuring electric charge values. The pulse's arrival time at the analyzer is considered only when the electric charge reaches its defined maximum value. Figure 12 shows a typical output of the LAPS meter. It shows a graph where bovine serum albumin solution in deionized water is tested with a flow rate of 10–50 μl/min. The lag time is plotted against the inverse flow rate. It is found that the lag time is inversely proportional to the flow rate. Also, the time delay between the event and the detection is inversely proportional to the velocity.

Pulse Modality Flow Sensors. Pulse modality flow sensors measure liquid flow through the integrated channel sidewall using a pulse modality [7]. Figure 13 shows an image of the sensor taken using a scanning electron microscope, a device that produces high-resolution images of a sample surface [8]. It clearly shows the sensing element, the channel and the electrode.

The sensor applies the principle of heat transfer where its output signal is tied to the relationship between sensing element temperature and flow rate, between sensing element resistivity and temperature. Figure 14 shows the relationship between sensing element temperature and flow velocity. This sensor is claimed to produce fast and highly sensitive signals for regulation of microflow in the range 0.01–10 ml/min.

Future Directions for Research

Microfluidic velocity sensors are based on very sensitive structures and materials. Their sensor systems are developed using complicated fabrication technology, sophisticated measuring apparatus and at high production cost [10]. These are issues that require immediate attention

because their commercialization is problematic. Microfluidic systems will achieve their full potential if micropumping operates at an optimum level where flow rate must be measurable and controllable based on the needs of the system. For an application that delivers protein to a microbioreactor at a precise rate using this miropumping operation then some feedback controls would be necessary to ensure that process disruption did not affect the delivery rate [3]. It is highly desirable for microfluidic systems to have necessary feedback controls to produce accurate flow rates.

Venturi Diode

Definition

A version of a no-moving-part fluidic diode consisting of two series-connected components: a flow contraction upstream and a diffuser immediately downstream.
A successful type of a fluidic diode particularly suited for operation at quite high operating frequencies. Its operation may be explained by considering the difference in the widths or diameters of the issuing jets in the two opposing flow direction. The difference is due to the flow separation from the walls of the contraction which lacks the diffuser property of keeping the flow attached.

Non-Newtonian; Viscoelastic; Relaxation;
Shear; Extensional

Definition

Subjected to an applied force, an elastic solid instantaneously deforms. The deformation is fully recovered with the removal of the force. In contrast, the deformation of a viscous fluid increases with time when a force is applied. With the removal of the force, a viscous fluid ceases to deform further, but any prior deformation remains. A viscoelastic material exhibits both elasticity and ▶ viscosity. Subjected to an applied force, it deforms and its deformation increases with time, i. e., it creeps. When the force is removed, only partial deformation is recovered instantaneously. It recovers more, but not all, of its deformation as time progresses. Depending on the time scale of interest, a viscoelastic material could behave solid-like or fluid-like or a combination of both.

Chemical and Physical Principles

Sir Isaac Newton proposed the law of viscosity in 1687 [1]. Subsequently, the analogous supposition, giving the modern form to the Newton hypothesis, was formulated by Navier and then by Stokes. Liquid with flow properties obeying the Newton hypothesis is called a Newton–Stokes liquid, or a Newtonian liquid. In a simple Newtonian shear flow, the shear stress is linearly proportional to the deformation rate,

$$\tau = \mu\dot{\gamma} \tag{1}$$

where τ is the shear stress and $\dot{\gamma} = \mathrm{d}\gamma/\mathrm{d}t$ is the shear rate or rate of shear deformation. The Newtonian viscosity, μ, is constant for a given temperature and is independent of shear rate or stress. Thus, a plot of shear stress versus shear rate at a given temperature is a straight line with a constant slope.

Another model describing the mechanical properties of materials originated in the seventeen century is Hooke's law for a linear elastic solid [1],

$$\sigma = E\varepsilon \tag{2}$$

where ε, σ and E are the strain, the stress and the elastic modulus, respectively.

Newton's law is satisfactory for describing the flow of simple liquids and gases with molecular weights less than $M_{\mathrm{wt}} \leq 1000\,\mathrm{g/mol}$ [2]. However, it is not adequate to describe the behaviors of polymer melts and simple liquids with the addition of high molecular weight macromolecules (polymers). For a given temperature, μ is no longer constant but depends on the flow conditions such as the shear rate $\dot{\gamma}(t)$ or the shear stress $\tau(t)$. Any fluid that does not obey the Newtonian relationship is termed as a non-Newtonian fluid.

The first person who paid attention to the effect of *viscoelasticity* was C. A. Coulomb in 1784 [1]. He showed that the damping in torsional oscillations of wires is caused by the viscoelasticity of the materials. Subsequently, it has been shown that fluids can also exhibit viscoelastic behavior, which has now been comprehensively documented over the last three decades. Some excellent references are *Viscoelastic Properties of Polymers* by Ferry [3], *The Dynamics of Polymeric Liquids* by Bird et al. [2] and *Rheological Phenomenon in Focus* by Boger and Walters [4].

Viscoelastic Behavior

Creep-and-recovery and stress relaxation experiments are the simple methods to illustrate viscoelasticity.

Creep and Recovery Tests

When a Newtonian fluid is stretched by a stress at $t = t_0$, as shown in Fig. 1a(1), the strain $\varepsilon(t)$ will increase linearly with time, see Fig. 1a(2). If the stress is removed at $t = t_{\mathrm{s}}$, the strain $\varepsilon(t)$ will remain at the level reached at $t = t_{\mathrm{s}}$, i. e., $\varepsilon(t_{\mathrm{s}})$.

When a Hookean solid is stretched, the strain $\varepsilon(t)$ will instantly increases proportionally to the stress to $\varepsilon(t_0)$, see Fig. 1a(3). $\varepsilon(t)$ will remain constant until the stress is removed at $t = t_{\mathrm{s}}$, at which time all the strain is recovered and $\varepsilon(t_{\mathrm{s}}) = 0$.

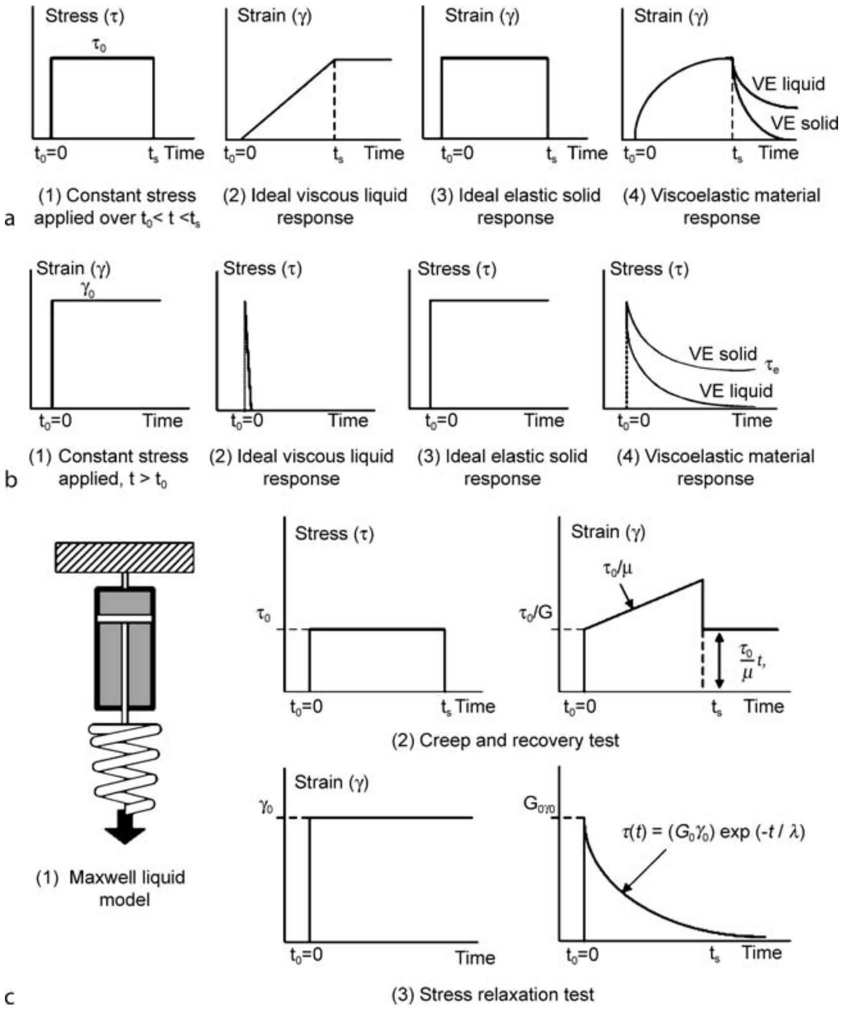
For a viscoelastic material under a constant applied stress, the strain $\varepsilon(t)$ shows a delay in response to the applied stress, see Fig. 1a(4). When the load is removed at $t = t_{\mathrm{s}}$ a viscoelastic liquid will recover partially its deformation at $t = t_{\mathrm{s}}$ over a period of time. Some deformation remains permanently. In contrast, for a viscoelastic solid, on load removal, the deformation recovery over time is relatively faster, and almost all the deformation may be recovered over a sufficiently long period of time.

Stress Relaxation Test

Figure 1b(1) shows at time $t = t_0$ a material is subjected to a strain step, and with the strain remains at this value for a prolong period of time. For a Newtonian fluid, the stress, $\tau(t)$, will increase suddenly with the sudden and step increase in strain. However, $\tau(t)$ will instantly drops to zero, see Fig. 1b(2). Thus, an immediate and complete stress relaxation occurs.

For a Hookean solid, the stress $\tau(t)$ remains constant after strain step at $t = t_0$, i. e., no stress relaxation occurs.

After the application of a strain step at $t = t_0$, both viscoelastic liquid and solid show a non-linear delay in stress relaxation as a function of their viscoelastic properties, see



Viscoelasticity, Figure 1 (**a**) Creep and recovery tests: (1) stress step (2) response of an ideal viscous liquid (3) response of an ideal elastic solid (4) response of two different viscoelastic materials, both are showing delayed recovery of deformation. (**b**) Stress relaxation tests: (1) strain step (2) ideal viscous liquid relaxation curve (3) ideal elastic solid relaxation curve (4) Stress relation curves of two viscoelastic materials, both are showing delayed relaxation. (**c**) (1) Schematic of Maxwell liquid model an its response to (2) creep recovery test and (3) stress relaxation test

Fig. 1b(4). For a viscoelastic liquid, a delayed but complete stress relaxation takes place if the period of observation is sufficiently long. However, for a viscoelastic solid, a delayed and partial stress relaxation takes place even after a long period of observation.

Mathematical Model for Viscoelastic Fluid Behavior

It is rather complex to describe viscoelastic behaviors mathematically. We will only focus here the simple, but representative Maxwell model for viscoelastic liquids. A mechanical analogue of a Maxwell liquid model is obtained by a serial combination of a spring and a dashpot, see Fig. 1c(1). If the individual strain rates of the spring and the dashpot respectively are $\dot{\varepsilon}_{\text{solid}}$ and $\dot{\varepsilon}_{\text{liquid}}$, then the total strain rate $\dot{\varepsilon}$ is given by the sum of these two components:

$$\dot{\varepsilon} = \dot{\varepsilon}_{\text{fluid}} + \dot{\varepsilon}_{\text{solid}}$$

$$\Rightarrow \quad \dot{\varepsilon} = \frac{\tau}{\mu} + \frac{\dot{\tau}}{G} \tag{3}$$

where G is the shear modulus.

Incorporating the Hooke's law of elasticity and Newton's law of viscosity with Eq. (3), the stress-strain relationship can be expressed as

$$\mu\dot{\varepsilon} = \tau + \lambda\dot{\tau} \tag{4}$$

where $\dot{\tau}$ is the time derivative of τ, $\lambda = \mu/G$ is the relaxation time. From Eq.(4), if a constant stress is applied to a Maxwell-model fluid, the strain rate will be constant and the strain will increase indefinitely, the so called creep phenomenon, see Fig 1c(2). If instead, a constant strain is applied to the fluid, the stress will decay as $\exp(-t/\lambda)$, the so called stress relaxation, see Fig. 1c(3). An important feature of the Maxwell model is its predominantly fluid-like response, see Fig. 1c. However, comparing Fig. 1c(2) and 1c(3) to Fig 1a(2) and 1a(4) respectively, it can be observed that the Maxell model is only an approximation to a viscoelastic liquid.

There are other models based on springs and dashpots such as the simple Kelvin–Voigt model for viscoelastic solid and the Burgers model. Reader is referred to [1–5] for details. Other elementary models are the dumbbell, bead-spring representations, network and kinetic theories. However, the most notable limitation of all these models is their restriction to small strain and strain rates [2, 3].

Viscoelastic Fluid Behaviors

Polymeric solutions are inherently viscoelastic due to their long molecular chains. Dilute polymeric solutions will be of interests for microfluidic and nanofluidic applications, due to their ease of implementation. Since the polymer coils in a dilute solution are isolated and independent in their molecular movements, their viscoelastic behavior can be explained by the deformation of the individual coil or molecule in the stream [2, 3]. As a result, the viscoelasticity of polymer solutions is generally attributed to the deformation of polymer chains and the consequent generation of unequal normal stresses.

Steady Shear Flows

For a one-dimensional steady shear flow of a fluid between two planes, the velocities of an infinitesimal element of fluid in the y- and z-directions are zero. The velocity in the x-direction is a function of y only. Note that in addition to the shear stress τ_{yx} (refer to τ subsequently) there are three normal stresses denoted by τ_{xx}, τ_{yy}, τ_{zz} within the sheared fluid. Weissenberg in 1947 [6] was the first to observe that the shearing motion of a viscoelastic fluid gives rise to unequal normal stresses, known as Weissenberg effects. Since the pressure in a non-Newtonian fluid cannot be defined, and as the normal stress differences [2, 3], $\tau_{xx} - \tau_{yy} = N_1$ and $\tau_{yy} - \tau_{zz} = N_2$, are more readily measured than the individual stresses, it is therefore customary to express N_1 and N_2 together with the shear stress τ as functions of the shear rate $\dot{\gamma}_{yx}$ to describe the viscoelastic behavior of a material in a simple shear flow.

The first and second normal stress differences N_1 and N_2can be expressed in terms of two coefficients, ψ_1 and ψ_2, defined as follows:

$$\psi_1 = \frac{N_1}{\gamma_{yx}^2} \quad \text{and} \quad \psi_2 = \frac{N_2}{\gamma_{yx}^2} \tag{5}$$

It is common that the first normal stress difference N_1 is higher than the shear stress τ. The ratio of N_1 to τ is often taken as a measure of how elastic a liquid is; specifically (N_1/τ) is referred as the recoverable shear.

Elongational Flow

Three main types of elongational flow are uniaxial, biaxial and planar. Although resistance to flow can be referred to loosely as an elongational or extensional viscosity (which further depends upon the type of elongational flow), this parameter generally is not constant.

For simplicity, consider the behavior of an incompressible fluid element which is being elongated at a constant strain rate $\dot{\varepsilon}$ in the x-direction (uniaxial extensional flow). For an incompressible fluid, the volume of the element must remain constant and therefore it must contract in both the y- and z-directions at the rate of $(\dot{\varepsilon}/2)$ for a system symmetrical in these directions. The three components of the velocity vector $\boldsymbol{V_i}$ are given by:

$$\boldsymbol{V_x} = \dot{\varepsilon}x\,, \quad \boldsymbol{V_y} = -\frac{\dot{\varepsilon}}{2}y\,, \quad \boldsymbol{V_z} = -\frac{\dot{\varepsilon}}{2}z \tag{6}$$

The rate of elongation in the x-direction can be written as:

$$\dot{\varepsilon} = \frac{\partial \boldsymbol{V_x}}{\partial x} \tag{7}$$

In uniaxial extension, the elongational viscosity μ_e can then be defined as:

$$\mu_e = \frac{\tau_{xx} - \tau_{yy}}{\dot{\varepsilon}} \quad \text{or} \quad \frac{\tau_{xx} - \tau_{zz}}{\dot{\varepsilon}} \tag{8}$$

The earliest determinations of elongational viscosity were for the simplest case of uniaxial extension or stretching of a fiber or filament of liquid. Trouton [7], and subsequently many other investigators, found that at low strain (or elongation) rates, the elongational viscosity μ_e was three times the shear viscosity μ. The ratio μ_e/μ is referred to as the Trouton ratio, T_r:

$$T_r = \frac{\mu_e}{\mu} = 3 \tag{9}$$

The value of 3 for Trouton ratio refers specifically to the viscosities in shear and elongation for an incompressible Newtonian fluid.

By analogy, the Trouton ratio for a non-Newtonian fluid, for which T_r is not necessary equal to three, can be defined as:

$$T_r = \frac{\mu_e(\dot{\varepsilon})}{\mu(\dot{\gamma})} \tag{10}$$

Since the Trouton ratio depends on both $\dot{\varepsilon}$ and $\dot{\gamma}$ in Eq. (10), there is some ambiguity in choosing their values. To provide a convenient estimate without this ambiguity, Jones et al. [8] proposed the following definition:

$$T_r = \frac{\mu_e(\dot{\varepsilon})}{\mu(\sqrt{3}\dot{\varepsilon})} \tag{11}$$

i. e., in the denominator, the shear viscosity is evaluated at $\dot{\gamma} = \sqrt{3}\,\dot{\varepsilon}$. They also suggested that for inelastic isotropic fluids, the Trouton ratio is equal to 3 for all values of $\dot{\varepsilon}$ and $\dot{\gamma}$ and any departure from the value of 3 can be ascribed unambiguously to *viscoelasticity*.

A common behavior of polymeric solutions [9–11] and polymer melts [12] is that the Trouton ratio is greater than three at moderate and higher deformation rate. Their typical behaviors are illustrated in Fig. 2, which show that the Trouton ratio can be a function of both strain and strain rate.

Dimensionless Parameters

The relaxation time (λ), which describes the time required for the polymer coil to relax from a deformed state back to its equilibrium configuration, is a key parameter for characterizing a viscoelastic fluid. For a fluid with large λ, the stresses relax slowly and the elastic effects can be observed even at low deformation rates. A fluid with small λ can also exhibit significant elastic effects provided that the deformation rate is high. Clearly, both the fluid characteristic time (the relaxation time) and the flow characteristic time (e. g. the inverse of the deformation rate) are crucial in determining the viscoelastic response of a viscoelastic liquid. For many polymeric liquids, λ lies between 10^{-3} s for dilute solutions and 10^3 s for concentrated solutions.

The relative importance of elasticity in a flow is often described by the Deborah number, De introduced by Reiner [13]. This number may be interpreted as the ratio of the magnitudes of the elastic forces to that of the viscous forces. It is defined as the ratio of a characteristic time (time scale) of the fluid λ to a characteristic time of the flow system t_{flow} [2]

$$\text{De} = \frac{\lambda}{t_{\text{flow}}} \tag{12}$$

The characteristic time of the fluid is often taken to be the largest time constant describing the slowest molecular motions, or else some mean time constant determined by linear viscoelasticity. The characteristic time may also be chosen as a time constant in a constitutive equation. The characteristic time for the flow is usually taken to be the time interval during which a typical fluid element experiences a significant sequence of kinematic events, for example the duration of a characteristic experimental observation. If the flow following a material particle is steady, the characteristic time can be the reciprocal of a characteristic strain rate.

Rheological Measurements

Rheological properties of the same polymeric solution measured in shear and elogational flows can be very different as discussed in earlier section. However, a cursory examination of current textbooks on rheology (e. g. Bird et al. [2], Ferry [3], Tanner [14]) shows that shear rheology dominates and research in extensional rheology is comparatively much more recent. The measurements of the shear properties of polymeric fluids are well established and a number of ▶ rheometers are available for both melts and dilute polymeric solutions. Lately, more efforts have been directed in measuring the extensional properties of fluids [8, 9, 15–19].

In practice, the steady shear and oscillatory tests are commonly conducted via rotational rheometers, and the extensional test is widely performed in *liquid filament rheometers* or *capillary breakup extensional rheometers* (CaBER).

Rotational Shear Measurements

Steady Shear Flow Curves Steady shear flow generally is a viscosity measurement on materials undergoing steady and continuous shear. A flow curve, viscosity (μ) versus shear rate ($\dot{\gamma}$), across a wide range of shear rate is often used to design pumps and mixing devices. This method is also used to provide flow behavior which indicates the relationship of shear rate to shear stress between suitable limits. A commonly observed feature of polymeric solutions is the shear thinning characteristic, i. e., the decrease of viscosity with increasing shear rate, which can be determined from this technique. This typical flow curve exhibits two Newtonian plateaus – one at low shear and another at high shear regimes. The shear thinning region lies between the two limiting conditions and may extend over a few decades of shear rate.

However, dynamic measurements, such as the oscillatory tests, are preferred in practice over the steady shear measurements for determining the viscoelastic properties of fluids. This is not only because of the difficulty in determining the first normal stress coefficient accurately, the determination of a fluid's viscosity by steady shear measurement is only a partial characterization of a viscoelastic fluid's properties.

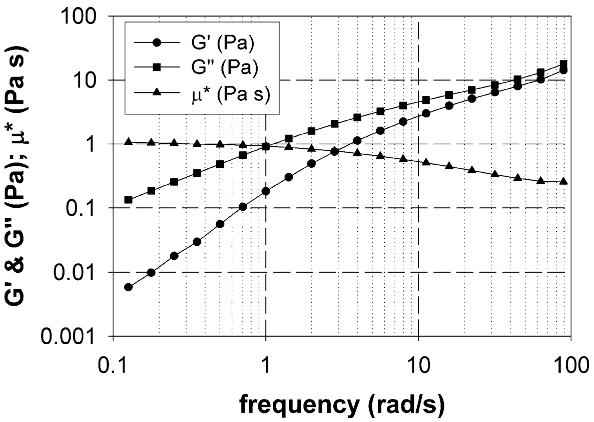
Dynamic Oscillatory Experiments The dynamic rheological properties of a polymeric solution can be determined by small-amplitude oscillation tests [2]. In small amplitude oscillatory measurements, a sinusoidally varying shear stress field is imposed on a fluid and the amplitude of the resulting shear strain and phase angle between the imposed stress and the strain is measured. The test is said to be in the *linear viscoelastic* regime if the strain is linearly proportional to the imposed stress and the response is sinusoidal [1, 5].

In practice, dynamic oscillatory measurements are sensitive probes of molecular structure and interactions, for examples in emulsions and dispersions. Oscillatory measurements probe emulsion structure without destroying it. This is accomplished by applying very small sinusoidal displacements or strains to the emulsion at controlled amplitude and frequency. In general, there are two mechanisms for a material to respond to a deformation:

- elastic energy storage (G', known as storage modulus), and
- viscous dissipation (G'', known as loss modulus).

G', which is proportional to the strain in-phase with the stress, provides information about the elasticity of a material. G'', the loss modulus, is proportional to the stress out-of-phase with the displacement. These parameters are termed the elastic and viscous loss moduli, G' & G'' respectively. The values of the respective stresses measured are divided by the appropriate strains, resulting in the respective moduli. The shapes of the curves for G' and G'' versus the test frequency ω for polymeric solutions are described by Ferry [3]. At low frequency, G' and G' are proportional to ω^2 and ω respectively. As frequency increases, the slope of these curves decreases, as illustrated in Fig. 3.

Qualitatively, the stress created by imposing oscillatory strains will be a function of the amplitude of strain, its frequency, and the properties of the polymeric solution. By applying sufficiently small strains, we can minimize the strain dependency from the material response. Thus, the amplitude of strain is no longer an important consideration, resulting in a *linear viscoelastic* response. Small



Viscoelasticity, Figure 3 Dynamic test: frequency oscillation sweep. For viscoelastic fluid of 1 wt% poly (ethylene-oxide)(PEO) in 55 wt% glycerol water. Molecular weight of PEO is 2×10^6 g/mol

strain measurements can be important for certain application as they do not adversely affect the structure of the fluid.

These linear viscoelastic dynamic moduli are functions of frequency. For a suspension or an emulsion material at low frequency, elastic stresses relax and viscous stresses dominate with the result that the loss modulus, G'', is higher than the storage modulus, G'. For a dilute solution, G'' is larger than G' over the entire frequency range but they approach each other at higher frequencies as shown in Fig. 3.

The Maxwell relaxation time is commonly evaluated from the first normal stress difference measurement,

$$\lambda_M = \frac{N_1}{2\dot{\gamma}^2\mu_0} \tag{13}$$

However, at zero deformation rate, where the simple fluid theory applies, can be evaluated from the oscillatory data by

$$\lambda_M^0 = \lim_{\dot{\gamma}\to 0}\frac{N_1}{2\dot{\gamma}^2\mu_0} = \lim_{\omega\to 0}\frac{G'}{\omega^2\mu_0} \tag{14}$$

It was shown that for water soluble polymeric solution such as Separan AP30, NP10 and Keltrol with polymer concentration less than approximately 1500, 5000, and 500 ppm, respectively, is independent of polymer concentration [20]. These observations were consistent with the molecular theories such as the Zimm theory, which states that at infinite dilution, the relaxation time is independent of polymer concentration and is given by

$$\lambda_z = 0.423\frac{[\mu]\,\mu_s M_{wt}}{RT} \tag{15}$$

where $[\mu]$ is the intrinsic viscosity [2, 3] and μ_s is the solvent viscosity.

By Cox–Mertz rule, for polymeric solutions at low frequency and shear rate in accordance with the simple fluid theory, the zero shear viscosity can be estimated by [2, 20]

$$\mu_0 = \lim_{\dot{\gamma}\to 0}\mu = \lim_{\omega\to 0}\left|\mu^*\right| = \lim_{\omega\to 0}\left(\frac{G''}{\omega}\right) \tag{16}$$

Key Research Findings

Extensional Rheological Measurement

Elongational or extensional flow of polymeric fluids are experienced in important industry processes, such as food dispersion, paints, adhesives, coating, inkjet printing, enhanced oil recovery, and lubrication. However, extensional properties cannot be determined from shear rheometry experiments.

Filament-stretching has been studied for obtaining extensional properties of polymeric solutions and melts. A comprehensive review of the flow dynamics of filament-stretching is provided by McKinley and Sridhar [9]. Subsequently, *liquid filament rheometers* or *capillary breakup extensional rheometers* (CaBER) has been developed for the characterization of the dynamics of complex fluids undergoing extensional flows.

Technical Aspect of CaBER Measurements

Recently, rheometer for measuring extensional properties is commercially available. It is called the CaBER 1 (the Capillary Breakup Extensional Rheometer). It was designed by the Cambridge Polymer Group and is manufactured by Thermo Haake. The measuring procedure involves the placing of a small quantity of sample fluid between two parallel plates. A fluid filament is formed when the sample fluid is subjected to a rapid extensional step strain, see Fig. 4. The filament evolution as a function of time is dictated by the surface tension and the viscoelastic stresses of the fluid. The surface tension is trying to *pinch off* the filament and the extensional properties of the sample are trying to prevent it. A laser micrometer measures the midpoint diameter of the gradually thinning fluid filament when the upper plate extends to its final position. From the measured data, several elongational rheological properties can be determined such as the extensional viscosity, evolution of the filament diameter as a function of time, the extensional deformation and deformation rate, and the filament break-up time.

In general, the changes of a fluid filament are governed by a balance of forces on the filament. Assuming that a fluid sample is at rest initially, and is subjected to a constant strain rate subsequently. With reference to the mid-diameter (D_{mid}) of the filament and ignoring the very small inertial effects [10], the governing equation can be expressed as

$$\mu_e\dot{\varepsilon}_0 \equiv \langle\tau_{zz} - \tau_{rr}\rangle = \frac{4F_z}{\pi D_{mid}^2} - \frac{2\rho g V_0}{\pi D_{mid}^2} - \frac{2\sigma}{D_{mid}} \tag{17}$$

where ρ and V_0 is the density of the sample fluid and the sample volume respectively. σ is the surface tension of the fluid, which has to be measured separately. g is the gravitational constant. F_z is the tensile force acting on the column ends, and $\langle\tau_{zz} - \tau_{rr}\rangle$ represents the non-Newtonian contribution to the average total normal stress difference over the filament cross section.

Equation (17) is model-dependent and the resulting solution to the differential equation depends on how the polymeric contribution to the stress varies with the rate of deformation. Solutions to this evolution equation have

Upper Convected Maxwell	$D_{mid}(t) = D_0\left(GD_0/\sigma\right)^{1/3}\exp(-t/3\lambda_c)$	λ_c, G/σ

been found for a number of models [17–19] and are summarized in Table 1.

The Apparent Extensional Viscosity

The evolution of filament diameter is driven by the capillary pressure and resisted by the extensional stress in the fluid. Thus, measurements can also be represented in terms of an apparent extensional viscosity, define as

$$\mu_{app}(\varepsilon) = \langle \tau_{zz} - \tau_{rr} \rangle / \dot{\varepsilon}(t) \qquad (18)$$

where under steady elongation flow, the natural-strain or Hencky strain [9] is given by

$$\varepsilon\,(0, t) = \dot{\varepsilon}_0 t = \ln(L(t)/L_0) = -2\ln(D(t)/D_0) \qquad (19)$$

Hence, the apparent viscosity can be written as,

$$\mu_{app}(\varepsilon) = \frac{\frac{2\sigma}{D_{mid}(t)}}{-\frac{2}{D_{mid}(t)}\frac{dD_{mid}}{dt}} = \frac{\sigma}{\frac{dD_{mid}}{dt}} \qquad (20)$$

Examples of Application

- Inkjet printing cartridge: a micro-entry flow (contraction flow) of a non-Newtonian fluid.
- Micro-injection molding: scaled-down version of injection molding (contraction flow).
- Flow focusing of emulsion: micro-contraction is used to generate emulsion droplet.
- Viscoelastic micro-mixer: elastically induced chaotic flow instabilities through contraction/expansion geometrical configuration in a microchannel.
- Microfluidics rectifier: a channel whose resistance to flow changes based on the direction of the flow.

Viscosity

Synonyms

Compactness; Plasticity

Definition

Viscosity is a measure of the resistance of a fluid to deform under shear stress. It describes a fluid's internal resistance to flow and may be thought of as the friction forces that act within a moving fluid. Viscosity can also be defined as the ratio of the shear stress to the strain rate.

Internal friction

Definition

The irreversible process by means of which the work done by a fluid on adjacent layers due to the action of shear forces is transformed into heat is defined as viscous dissipation.

Overview

The equation of continuity and the thermal energy balance on a differential element fixed in a pure flowing fluid can be written as follows:

$$
\begin{aligned}
-\frac{1}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t} &= \nabla\cdot\boldsymbol{v} \\
\rho\frac{\mathrm{D}U}{\mathrm{D}t} &= -\nabla\cdot\boldsymbol{q} - p\,(\nabla\cdot\boldsymbol{v}) - \bar{\boldsymbol{\tau}}:\nabla\boldsymbol{v}
\end{aligned}
\tag{1}
$$

in which U is the specific internal energy of the fluid, p the pressure, $\boldsymbol{v}$ the velocity vector, $\boldsymbol{q}$ the heat flux, ρ the fluid density, t the time and $\bar{\boldsymbol{\tau}}$ the viscous tensor.
The second term on the right-hand side of Eq. (1) represents the reversible work done by the fluid against the external pressure field; this term is linked to the compressibility of the fluid and is known in the literature as *flow work*. The third term on the right-hand side of Eq. (1) is linked to the work done by the fluid on adjacent layers due to the action of the shear forces; this work is transformed

V

into heat by means of an irreversible process called *viscous dissipation* in the English language literature and as *internal friction* in the Russian literature.

The effect of the viscous dissipation on heat transfer is significant especially for high-velocity flows, highly viscous flows even at moderate velocities, for fluids with a moderate Prandtl number and moderate velocities with small wall-to-fluid temperature difference or with low wall heat fluxes and flowing through microchannels.

Basic Methodology

Since the internal energy of a real fluid can be related to the temperature and to the fluid specific heat by means of the equation

$$\mathrm{d}U = c_\mathrm{V}\,\mathrm{d}T + \left[T\left(\frac{\partial p}{\partial T}\right)_\mathrm{V} - p\right]\mathrm{d}V \tag{2}$$

one can write the total derivative of the internal energy in terms of the fluid temperature as follows:

$$\frac{\mathrm{D}U}{\mathrm{D}t} = \left[T\left(\frac{\partial p}{\partial T}\right)_\mathrm{V} - p\right]\frac{\mathrm{D}V}{\mathrm{D}t} + c_\mathrm{V}\frac{\mathrm{D}T}{\mathrm{D}t} \tag{3}$$

where V is the specific volume of fluid, T is the absolute fluid temperature and c_V is the specific heat at constant volume.

The continuity equation allows one to write the derivative term of the fluid volume in the form

$$\frac{\mathrm{D}V}{\mathrm{D}t} = \frac{\mathrm{D}}{\mathrm{D}t}\left(\frac{1}{\rho}\right) = -\frac{1}{\rho^2}\frac{\mathrm{D}\rho}{\mathrm{D}t} = \frac{1}{\rho}\left(\nabla\cdot\boldsymbol{v}\right) \tag{4}$$

By combining Eq. (4) with Eq. (3) and the thermal energy balance (Eq. (1)), one obtains

$$\rho c_\mathrm{V}\frac{\mathrm{D}T}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{q} - T\left(\frac{\partial p}{\partial T}\right)_\mathrm{V}\left(\nabla\cdot\boldsymbol{v}\right) - \bar{\boldsymbol{\tau}} : \nabla\boldsymbol{v} \tag{5}$$

in which the energy balance is expressed by means of the fluid temperature and the physical properties of the fluid. In Eq. (5) it is evident that the reversible work done against the pressure field is linked to the fluid compressibility. More explicitly, if one considers the definition of the thermal expansion coefficient (β) and of the volume compressibility (χ)

$$\beta = -\frac{1}{\rho}\left(\frac{\partial\rho}{\partial T}\right)_\mathrm{p} \quad \chi = \frac{1}{\rho}\left(\frac{\partial\rho}{\partial p}\right)_\mathrm{T} \tag{6}$$

the thermal energy equation for viscous flows can be written as follows:

$$\begin{aligned}\rho c_\mathrm{V}\frac{\mathrm{D}T}{\mathrm{D}t} &= -\nabla\cdot\boldsymbol{q} - \frac{\beta}{\chi}T\left(\nabla\cdot\boldsymbol{v}\right) - \bar{\boldsymbol{\tau}} : \nabla\boldsymbol{v}\\ &= -\nabla\cdot\boldsymbol{q} + \frac{\beta}{\chi}T\left[\frac{1}{\rho}\frac{\mathrm{D}\rho}{\mathrm{D}t}\right] - \bar{\boldsymbol{\tau}} : \nabla\boldsymbol{v}\end{aligned} \tag{7}$$

By remembering the following relation between the fluid specific heats:

$$c_\mathrm{p} - c_\mathrm{V} = T\left[\left(\frac{\partial V}{\partial T}\right)_\mathrm{p}\frac{\mathrm{d}p}{\mathrm{d}T} + \left(\frac{\partial p}{\partial T}\right)_\mathrm{V}\frac{\mathrm{d}V}{\mathrm{d}T}\right] \tag{8}$$

the thermal energy equation (Eq. (7)) can be expressed in the following alternative form:

$$\rho c_\mathrm{p}\frac{\mathrm{D}T}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{q} + \beta T\frac{\mathrm{D}p}{\mathrm{D}t} - \bar{\boldsymbol{\tau}} : \nabla\boldsymbol{v} \tag{9}$$

in which the fluid specific heat at constant pressure is involved. Equation (9) is the version of the thermal energy quoted in many textbooks [1, 2]. For Fourier fluids the first term on the right-hand side of Eq. (9) can be expressed in terms of temperature gradient by using the Fourier law:

$$-\nabla\cdot\boldsymbol{q} = \nabla\cdot\left(k\nabla T\right) = k\nabla^2 T \tag{10}$$

where the last equality is obtained only for fluids with a constant thermal conductivity.

It is possible to demonstrate that, if the working fluid is Newtonian, the *viscous dissipation* term can be written as follows (i. e. in Cartesian coordinates):

$$\begin{aligned}\bar{\boldsymbol{\tau}} : \nabla\boldsymbol{v} &= -\mu\Phi\\ &= -\mu\left[-\frac{2}{3}\left(\nabla\cdot\boldsymbol{v}\right)^2 + 2\left(\frac{\partial v_x}{\partial x}\right)^2\right.\\ &\quad + 2\left(\frac{\partial v_y}{\partial y}\right)^2 + 2\left(\frac{\partial v_z}{\partial z}\right)^2 + \left(\frac{\partial v_z}{\partial y} + \frac{\partial v_y}{\partial z}\right)^2\\ &\quad \left. + \left(\frac{\partial v_x}{\partial z} + \frac{\partial v_z}{\partial x}\right)^2 + \left(\frac{\partial v_y}{\partial x} + \frac{\partial v_x}{\partial y}\right)^2\right]\end{aligned} \tag{11}$$

Equation (11) provides evidence that viscous heating can be considered as the sum of two terms:

- the rate of viscous dissipation due to the contribution of the density variation; and
- the rate of viscous dissipation for an incompressible fluid (Φ_inc).

$$\bar{\boldsymbol{\tau}} : \nabla \boldsymbol{v} = -\mu\Phi = -\mu\left[-\frac{2}{3}(\nabla\cdot\boldsymbol{v})^2 + \Phi_{\text{inc}}\right]$$
$$= -\mu\left[-\frac{2}{3}\frac{1}{\rho^2}\left(\frac{\mathrm{D}\rho}{\mathrm{D}t}\right)^2 + \Phi_{\text{inc}}\right] \quad (12)$$

If the fluid density is considered as a function of the pressure and of the temperature ($\rho = \rho(p, T)$), by using the definition of the volume compressibility and of the coefficient of thermal expansion, it is possible to write

$$\frac{\mathrm{d}\rho}{\rho} = -\beta\,\mathrm{d}T + \chi\,\mathrm{d}p \quad (13)$$

For this reason the viscous dissipation term for a real fluid can be written as follows:

$$\bar{\boldsymbol{\tau}} : \nabla \boldsymbol{v} = -\mu\Phi = -\mu\left[-\frac{2}{3}\left(\chi\frac{\mathrm{D}p}{\mathrm{D}t} - \beta\frac{\mathrm{D}T}{\mathrm{D}t}\right)^2 + \Phi_{\text{inc}}\right] \quad (14)$$

Thus, the general expression of the thermal energy equation for a real Newtonian fluid becomes

$$\rho c_{\mathrm{p}}\frac{\mathrm{D}T}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{q} + \beta T\frac{\mathrm{D}p}{\mathrm{D}t} + \mu\left[-\frac{2}{3}\left(\chi\frac{\mathrm{D}p}{\mathrm{D}t} - \beta\frac{\mathrm{D}T}{\mathrm{D}t}\right)^2 + \Phi_{\text{inc}}\right] \quad (15)$$

Table 1 reports the expressions of the viscous dissipation term for an incompressible fluid (Φ_{inc}) with constant properties for different geometry coordinates.

In Table 2 are quoted the values assumed by the volume compressibility and by the coefficient of thermal expansion for a selection of liquids and gases. It is evident that the liquids are in general characterized by very low values of compressibility. On the contrary, it is evident that many liquids have a value of the coefficient of thermal expansion that cannot be considered negligible.

From Eq. (15) it is possible to derive the following particular expressions of the thermal energy equation as a function of the fluid considered:

1. *Ideal gas* ($\beta = 1/T$, $\chi = 1/p$)

$$\rho c_{\mathrm{p}}\frac{\mathrm{D}T}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{q} + \frac{\mathrm{D}p}{\mathrm{D}t} + \mu\left[-\frac{2}{3}\left(\frac{1}{p}\frac{\mathrm{D}p}{\mathrm{D}t} - \frac{1}{T}\frac{\mathrm{D}T}{\mathrm{D}t}\right)^2 + \Phi_{\text{inc}}\right] \quad (16)$$

2. *Incompressible fluid* ($\beta = 0$, $\chi = 0$)

$$\rho c_{\mathrm{p}}\frac{\mathrm{D}T}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{q} + \mu\Phi_{\text{inc}} \quad (17)$$

3. *Real fluid* ($\beta \neq 0$, $\chi = 0$)

$$\rho c_{\mathrm{p}}\frac{\mathrm{D}T}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{q} + \beta T\frac{\mathrm{D}p}{\mathrm{D}t} + \mu\left[-\frac{2}{3}\left(\beta\frac{\mathrm{D}T}{\mathrm{D}t}\right)^2 + \Phi_{\text{inc}}\right] \quad (18)$$

4. *Real fluid* ($\beta = 0$, $\chi \neq 0$)

$$\rho c_{\mathrm{p}}\frac{\mathrm{D}T}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{q} + \mu\left[-\frac{2}{3}\left(\chi\frac{\mathrm{D}p}{\mathrm{D}t}\right)^2 + \Phi_{\text{inc}}\right] \quad (19)$$

As highlighted by Toor [3], observing the typical values of the thermal expansion coefficients and of the volume compressibility of the selection of liquids quoted in Table 2, it is possible to note that in general for liquids small changes in density allow the compressibility contribution to the dissipation function to be neglected so that it is possible to write

$$\Phi \cong \Phi_{\text{inc}} \quad (20)$$

For these reasons the following version of the thermal energy equation can be used with real liquids:

5. *Real liquids* ($\beta \neq 0$, $\chi = 0$)

$$\rho c_{\mathrm{p}}\frac{\mathrm{D}T}{\mathrm{D}t} = -\nabla\cdot\boldsymbol{q} + \beta T\frac{\mathrm{D}p}{\mathrm{D}t} + \mu\Phi_{\text{inc}} \quad (21)$$

V

This version of the thermal energy can be considered appropriate especially for liquids characterized by large values of the thermal expansion coefficient and subject to large pressure gradients; this can be the case for microchannels in which large pressure drops per unit length are ordinary for low hydraulic diameters.

If the thermal energy equation is used in order to study laminar flow forced convection in microchannels, the expression of the thermal energy equation can be simplified.

In this case, the velocity has only one nonzero component, along the axial direction z, and Eq. (15) can be written as

Viscous Dissipation, Table 1 The expressions of the viscous dissipation term for incompressible fluids with constant properties

Coordinates	Φ_{inc}
Rectangular	$2\left(\frac{\partial v_x}{\partial x}\right)^2+2\left(\frac{\partial v_y}{\partial y}\right)^2+2\left(\frac{\partial v_z}{\partial z}\right)^2+\left(\frac{\partial v_z}{\partial y}+\frac{\partial v_y}{\partial z}\right)^2+\left(\frac{\partial v_x}{\partial z}+\frac{\partial v_z}{\partial x}\right)^2+\left(\frac{\partial v_y}{\partial x}+\frac{\partial v_x}{\partial y}\right)^2$
Cylindrical	$2\left(\frac{\partial v_r}{\partial r}\right)^2+2\left(\frac{1}{r}\left(\frac{\partial v_\theta}{\partial \theta}+v_r\right)\right)^2+2\left(\frac{\partial v_z}{\partial z}\right)^2+\left(\frac{\partial v_\theta}{\partial z}+\frac{1}{r}\frac{\partial v_z}{\partial \theta}\right)^2+\left(\frac{\partial v_z}{\partial r}+\frac{\partial v_r}{\partial z}\right)^2+\left(\frac{1}{r}\frac{\partial v_r}{\partial \theta}+r\frac{\partial(v_\theta/r)}{\partial r}\right)^2$
Spherical	$2\left(\frac{\partial v_r}{\partial r}\right)^2+2\left(\frac{1}{r}\left(\frac{\partial v_\theta}{\partial \theta}+v_r\right)\right)^2+2\left(\frac{1}{r\sin\theta}\frac{\partial v_\phi}{\partial \phi}+\frac{v_r}{r}+\frac{v_\theta\cot\theta}{r}\right)^2+\left(r\frac{\partial(v_\theta/r)}{\partial r}+\frac{1}{r}\frac{\partial v_r}{\partial \theta}\right)^2$ $+\left(\frac{1}{r\sin\theta}\frac{\partial v_r}{\partial \phi}+r\frac{\partial(v_\phi/r)}{\partial r}\right)^2+\left(\frac{\sin\theta}{r}\frac{\partial(v_\phi/\sin\theta)}{\partial \theta}+\frac{1}{r\sin\theta}\frac{\partial v_\theta}{\partial \phi}\right)^2$

follows:

$$\rho c_p\left[\frac{\partial T}{\partial t}+v_z\frac{\partial T}{\partial z}\right]=-\nabla\cdot\boldsymbol{q}+\beta T\left[\frac{\partial p}{\partial t}+v_z\frac{\partial p}{\partial z}\right]+\mu\left[-\frac{2}{3}\left(\chi\left[\frac{\partial p}{\partial t}+v_z\frac{\partial p}{\partial z}\right]-\beta\left[\frac{\partial T}{\partial t}+v_z\frac{\partial T}{\partial z}\right]\right)^2+\Phi'_{inc}\right] \quad (22)$$

Some time after the flow has started, the time variation of the temperature approaches zero if the boundary conditions are independent of time. Assuming a steady-state axial pressure distribution and a fully developed velocity field inside the microchannel, the energy equation becomes:

Viscous Dissipation, Table 2 Typical values of the volume compressibility and of the coefficient of thermal expansion for a selection of liquids and gases

6. *Steady-state laminar flow in microchannels (fully developed velocity):*

$$\rho c_p v_z\frac{\partial T}{\partial z}=-\nabla\cdot\boldsymbol{q}+\beta T v_z\frac{\partial p}{\partial z}+\mu\left[-\frac{2}{3}\left(\chi v_z\frac{\partial p}{\partial z}-\beta v_z\frac{\partial T}{\partial z}\right)^2+\Phi'_{inc}\right]\quad \text{(for gases)} \quad (23)$$

$$\rho c_p v_z\frac{\partial T}{\partial z}=-\nabla\cdot\boldsymbol{q}+\beta T v_z\frac{\partial p}{\partial z}+\mu\Phi'_{inc}\quad \text{(for liquids)} \quad (24)$$

where Φ'_{inc} for incompressible laminar flow is given by

$$\Phi'_{inc}=\nabla v_z\cdot\nabla v_z \quad (25)$$

For rectangular and circular geometries the complete expression of Φ'_{inc} is reported in Table 3. It is interesting to observe that, for gases for which Eq. (20) holds, Eqs. (23) and (24) coincide.

In Eq. (24), written for liquids in microchannels, the flow work term is conserved in the energy balance because its role, especially in very fine microchannels, can be important since the pressure gradient along the tube is inversely proportional to the square of the hydraulic diameter of the channel:

$$-\frac{\partial p}{\partial z}=2f\,\mathrm{Re}\frac{\mu W}{D_h^2} \quad (26)$$

Viscous Dissipation, Table 3 The expressions of the dissipation function for fully developed incompressible laminar flow

Coordinates	Φ'_{inc}
Rectangular	$\left(\frac{\partial v_z}{\partial y}\right)^2+\left(\frac{\partial v_z}{\partial x}\right)^2$
Cylindrical	$\left(\frac{\partial v_z}{\partial r}\right)^2$

in which f is the Fanning friction factor, Re is the Reynolds number and W is the average fluid velocity.

By considering Eqs. (24) and (25) it is evident that the flow work term and the viscous dissipation term have opposite signs (negative and positive, respectively). This fact underlines that the viscous dissipation plays the role of a distributed heat source inside the fluid; on the contrary the fluid thermal expansion cools the flow like a distributed heat sink. In a tube, since these two effects are locally proportional to $(\partial v_z/\partial r)^2$ and to v_z respectively, the heat sink prevails in the central region of the channel and the heat source dominates in the wall region. The thermal energy generated mainly near the wall region due to the viscous dissipation is absorbed near the channel central region due to the flow work effect.

In general, it is recommended to use Eqs. (23) and (24) in dimensionless form. To this extent, as suggested by Shah and London [4] and Dryden [5], viscous dissipation effects for internal flows can be captured by introducing the Brinkman number:

$$\mathrm{Br} = \frac{\mu W^2}{k\Delta T_{\mathrm{ref}}} \tag{27}$$

in which ΔT_{ref} indicates a characteristic temperature difference for the specific problem considered (i. e. the difference between the wall temperature and the entrance temperature) and k is the fluid thermal conductivity.

For constant axial wall temperature boundary conditions (T boundary conditions) (see ►convective heat transfer in microchannels) the characteristic temperature difference ΔT_{ref} is defined as the difference between the fluid average bulk temperature and the external temperature.

For constant axial heat flux boundary conditions (H1 boundary conditions) the characteristic temperature difference to use in the definition of the Brinkman number is chosen equal to (q_{w}/k), in which q_{w} is the linear heat flux imposed at the walls of the channels.

When Eqs. (10) and (20) hold and the fluid has constant properties, the momentum and the thermal energy equations for steady-state laminar flow in microchannels with a fully developed velocity profile in dimensionless form become

$$\begin{cases} \nabla^{*2} V_z = -p^* \\ V_z \dfrac{\partial\theta}{\partial z^+} = \nabla^{*2}\theta - 2 f\,\mathrm{Re}\,\mathrm{Br}\,(\beta\Delta T_{\mathrm{ref}})\, V_z\theta + \mathrm{Br}\,\Phi'^{*}_{\mathrm{inc}} \end{cases} \tag{28}$$

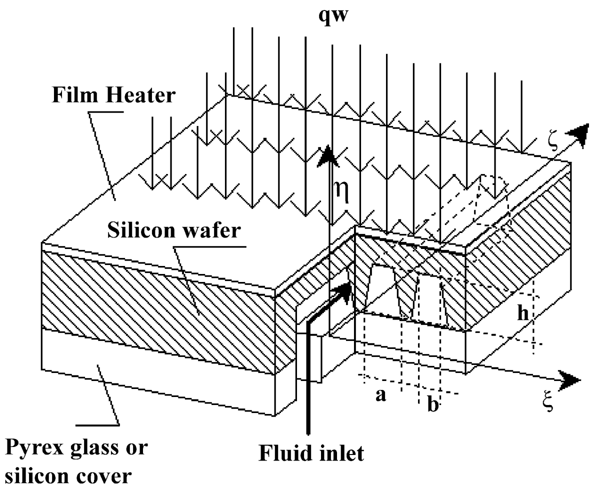
in which the following dimensionless quantities are introduced:

$$\begin{aligned} z^+ &= \frac{z}{D_h \mathrm{Re}\,\mathrm{Pr}}\,; & \nabla^* &= D_h\nabla\,; \\ V_z &= \frac{v_z}{W}\,; & p^* &= -\frac{D_h^2}{\mu W}\frac{\partial p}{\partial z}\,; \\ \theta &= \frac{T-T_0}{\Delta T_{\mathrm{ref}}}\,; & \Phi'^{*}_{\mathrm{inc}} &= \nabla^* V_z \cdot \nabla^* V_z \end{aligned} \tag{29}$$

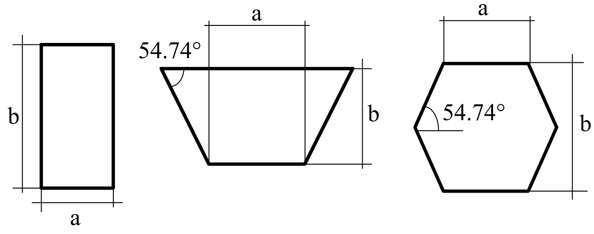
Examples of Application

Let us consider the silicon microchannel heat sink shown in Fig. 1; the microchannels obtained by chemical etching on the silicon wafer are in general closed by a Pyrex glass cover bonded to the substrate or by silicon wafer. A liquid flows through the channels; due to the small size of the microchannels the flow is typically laminar. The microchannels have an axially unchanging cross-section with area equal to Ω and a wetted perimeter equal to Γ. A fixed linear power q_{w} is imposed on the top of the silicon substrate while all the other outside walls can be considered as adiabatic. In silicon heat sinks, owing to the high thermal conductivity of the silicon, the temperature gradient in the silicon substrate is very limited and temperature field in the solid is close to isothermal. When a Pyrex cover is used to close the heat sink, three walls of the microchannel work with a constant temperature; on the contrary, the Pyrex side can be considered adiabatic. In general, the ratio between the thermal conductivity of the silicon and of the liquid assumes very high values, and the same occurs for the ratio between the length and the hydraulic diameter of the microchannel. For these reasons the microchannels can be conveniently studied as "long ducts" under a classical H1 thermal boundary condition with three sides having an imposed uniform temperature and one side (the Pyrex side) as adiabatic (*3bc* version; see ►convective heat transfer in microchannels). Conversely, when a silicon cover is used to close the microchannels, all the boundaries can be considered as isothermal; it is possible to use the H1 thermal boundary condition, with four sides having an imposed uniform temperature (*4bc* version; see ►convective heat transfer in microchannels).

For silicon microchannels produced by chemical etching the shape of the channels depends on a variety of factors such as the crystallographic nature of the silicon used. For example, when a KOH anisotropic etching technique is employed in ⟨100⟩ or ⟨110⟩ silicon, the microchannels have a trapezoidal cross-section (with an apex angle of 54.74° imposed by the crystallographic morphology of the silicon) or a rectangular cross-section respectively. In this analysis, KOH-etched microchannels having trapezoidal,



Viscous Dissipation, Figure 1 Schematic of a silicon heat sink



Viscous Dissipation, Figure 2 Rectangular, trapezoidal and double-trapezoidal KOH-etched microchannels

hexagonal (obtained by gluing together two trapezoidal channels) and rectangular cross-sections are considered (see Fig. 2). Each cross-section is characterized by the aspect ratio α defined as the ratio between the height (b) and the minimum width (a) of the channel (see Fig. 2).

By applying Eqs. (28) to model the heat transfer process in the microchannels and considering the flow with constant properties and being thermally and hydrodynamically fully developed, one obtains

$$\begin{cases} \nabla^{*2} V_z = -p^* \\ V_z \dfrac{\partial \theta}{\partial z^+} = \nabla^{*2}\theta + \mathrm{Br}\left[\nabla^* V_z \cdot \nabla^* V_z\right] \end{cases} \tag{30}$$

where the liquid is considered as incompressible ($\beta = 0$) and $\Delta T_{\mathrm{ref}} = q_{\mathrm{w}}/k$ is used in the definition of the dimensionless temperature and the Brinkman number (see ►convective heat transfer in microchannels).

Further simplification can be made by considering that in the fully developed thermal region of a heated duct the temperature profile continues to change axially but the "relative temperature shape" of the profile no longer changes. Resorting to the definition of thermally fully developed region for the H1 boundary condition, it is possible to demonstrate (see ►viscous heating) that

$$\frac{\partial \theta}{\partial z^+} = \frac{\partial \theta_{\mathrm{b}}}{\partial z^+} = \frac{1}{\Omega^*} + 2\mathrm{Br} f\,\mathrm{Re} \tag{31}$$

where Ω^* is the dimensionless area of the cross-section ($\Omega^* = \Omega/D_{\mathrm{h}}^2$) and θ_{b} is the fluid bulk temperature. The momentum balance equation is solved by using the no-slip boundary condition at the wall which means considering negligible any rarefaction effect. The complete set of boundary conditions is thus

$$\begin{cases} V_z|_{\Gamma} = 0 \quad \theta|_{\Gamma} = 0 & \text{(4 version)} \\ V_z|_{\Gamma} = 0 \quad \left.\dfrac{\partial \theta}{\partial n}\right|_{\Gamma_{\mathrm{b}}^*} = 0 \quad \theta|_{\Gamma^* - \Gamma_{\mathrm{b}}^*} = 0 & \text{(3 version)} \end{cases} \tag{32}$$

where Γ_{b}^* is the dimensionless (divided by the hydraulic diameter) length of the adiabatic boundary of the microchannels.

From the dimensionless temperature distribution the value of the fluid bulk temperature can be computed as

$$\theta_{\mathrm{b}} = \frac{1}{\Omega^*} \int_{\Omega^*} V_z \theta \, \mathrm{d}\Omega^* \tag{33}$$

The local Nusselt number along the walls of the microchannels can be calculated as follows:

$$\mathrm{Nu}_{\mathrm{l}} = -\frac{1}{\theta_{\mathrm{b}}} n \cdot \nabla^* \theta \Big|_w \tag{34}$$

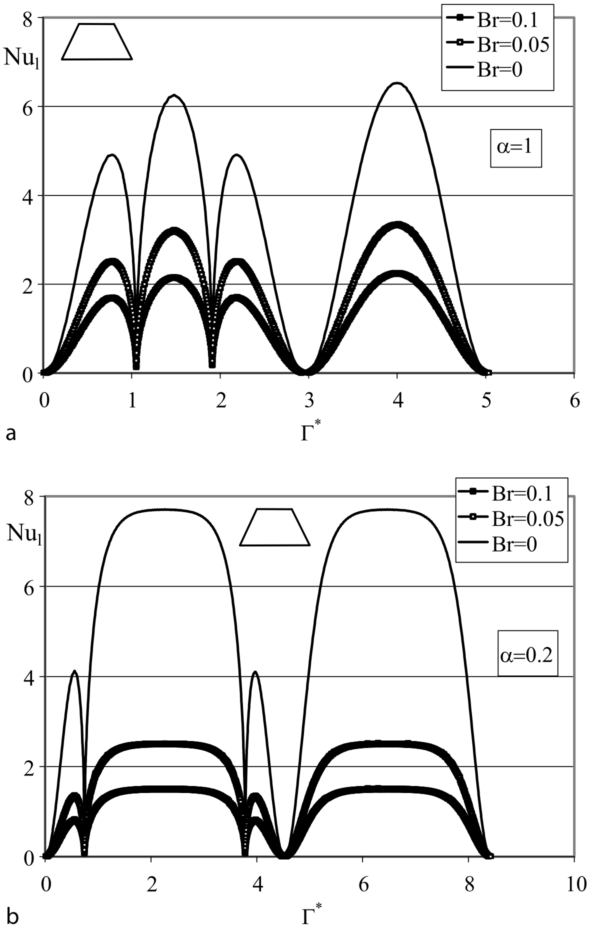
where n is the versor normal to the wall.

By averaging the local Nusselt number along the heated perimeter one can obtain the thermally fully developed mean Nusselt number:

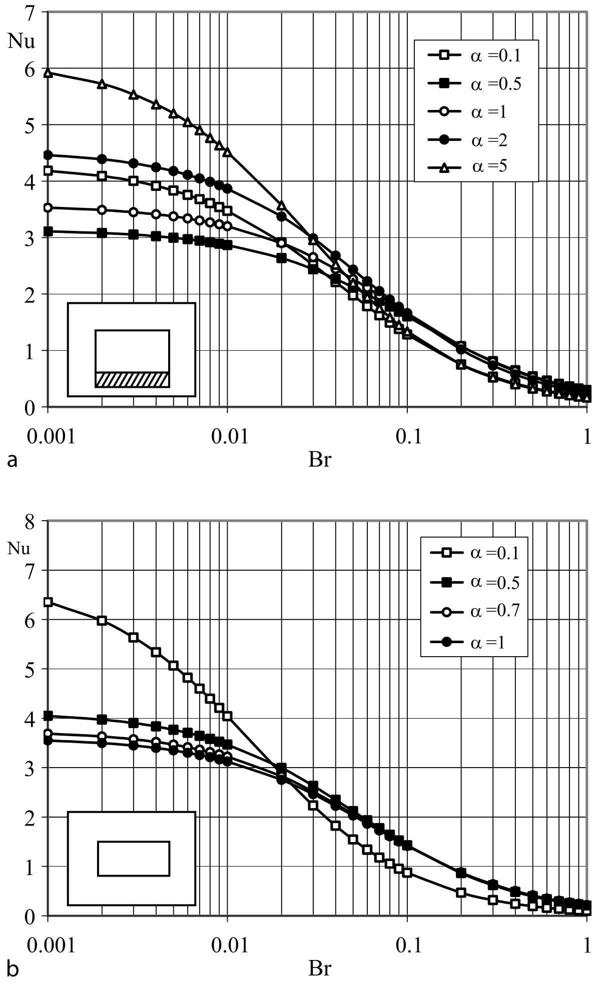
$$\mathrm{Nu} = \frac{1}{\Gamma_{\mathrm{h}}^*} \int_{\Gamma_{\mathrm{h}}^*} \mathrm{Nu}_{\mathrm{l}} \, \mathrm{d}\Gamma^* = -\frac{1}{\Gamma_{\mathrm{h}}^* T_{\mathrm{b}}} \int_{\Gamma_{\mathrm{h}}^*} n \cdot \nabla T \, \mathrm{d}\Gamma^* = -\frac{1}{\Gamma_{\mathrm{h}}^* T_{\mathrm{b}}} \tag{35}$$

where Γ_{h}^* is the dimensionless heated perimeter ($\Gamma_{\mathrm{h}}^* = \Gamma^*$ (4bc version), $\Gamma_{\mathrm{h}}^* = \Gamma^* - \Gamma_{\mathrm{b}}^*$ (3bc version)).

The numerical solution of the problem defined by Eqs. (31) and (32) has been presented by Morini and Spiga [6]. In Fig. 3 the trends of the local Nusselt number along the perimeter of two trapezoidal microchannels having aspect ratio α equal to 1 (Fig. 3a) and 0.2 (Fig. 3b) with



Viscous Dissipation, Figure 3 Local Nusselt number along the perimeter of two trapezoidal microchannels with four heated sides for (**a**) $\alpha = 1$ and (**b**) $\alpha = 0.2$ as a function of the Brinkman number



Viscous Dissipation, Figure 4 Average fully developed Nusselt number as a function of the Brinkman number for rectangular silicon microchannels with (**a**) three and (**b**) four sides heated

four heated sides are shown as a function of the Brinkman number. It is evident that the convective heat transfer coefficient presents strong variations along the perimeter of the microchannel; in particular, the value of the local Nusselt number approaches zero near the corners of the channels where the fluid tends to be stagnant. When the aspect ratio decreases the longer sides tend to be characterized by a more uniform value of the local convective heat transfer coefficient. Figure 3 provides evidence for the reduction of the local values of the Nusselt numbers when the Brinkman number increases; when the effect of the viscous forces is significant ($Br > 0.001$) the local Nusselt numbers tend to decrease as an effect of the reduction of the temperature gradients at the walls due to the viscous internal heat production.

The average fully developed Nusselt number for rectangular silicon microchannels is plotted as a function of the Brinkman number in Fig. 4 with three (Fig. 4a) and four (Fig. 4b) sides heated respectively.

Looking at Fig. 4b, it is possible to note that in general the Nusselt number is higher for cross-sections having lower aspect ratios if the viscous dissipation is negligible ($Br < 0.001$). For large Brinkman numbers this rule is reversed; in fact, for large Brinkman numbers the cross-sections with lower aspect ratios exhibit lower Nusselt numbers.

It is possible to demonstrate analytically [7] that the link between the average Nusselt and Brinkman numbers can be expressed by means of a general relationship for circular and non-circular channels:

$$\overline{Nu}_{H1}(Br) = \frac{\overline{Nu}_{H1}}{1 + \sigma Br} \tag{36}$$

where $\overline{Nu}_{H1}$ is the fully developed value of the Nusselt number when $Br = 0$ (the values assumed by $\overline{Nu}_{H1}$ for the most common microchannel cross-sectional geometries are reported in ►convective heat transfer in microchannels) and σ is a parameter depending on the geometry of the channel cross-section (by means of the aspect ratio α) and on the combination of heated and adiabatic sides of the channel.

In Table 4 the values of σ calculated numerically for rectangular, trapezoidal and double-trapezoidal microchannels having three and four sides heated respectively are listed. Using these data and Eq. (36) it is possible to calculate the value assumed by the fully developed Nusselt number as a function of the Brinkman number in KOH-etched silicon microchannels. For the sake of completeness, it can be useful to remember that for circular microtubes with prescribed wall heat flux, the analytical value of σ is equal to $48\pi/11$ and the fully developed average Nusselt number (Nu_0) is equal to $48/11$.

In order to compare the thermal performances of silicon microheat sinks with rectangular or trapezoidal microchannels it is possible to use the *area goodness factor* defined as follows:

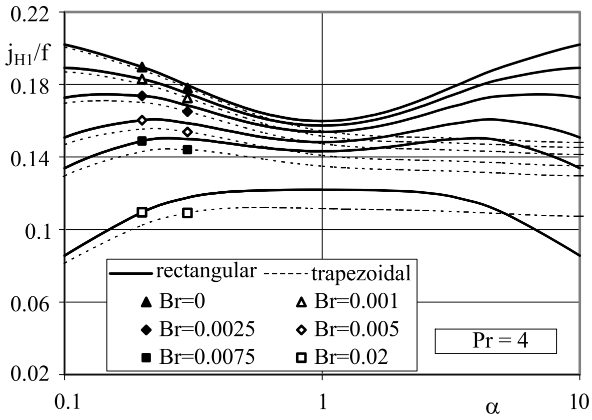
$$\frac{j}{f} = \frac{Nu\,Pr^{-1/3}}{f\,Re} \tag{37}$$

This factor was introduced by Shah and London [4] in order to compare different kinds of heat exchangers. From Eq. (37) it is evident that this factor depends only on the Brinkman number for the fully developed laminar flow of a specified fluid.

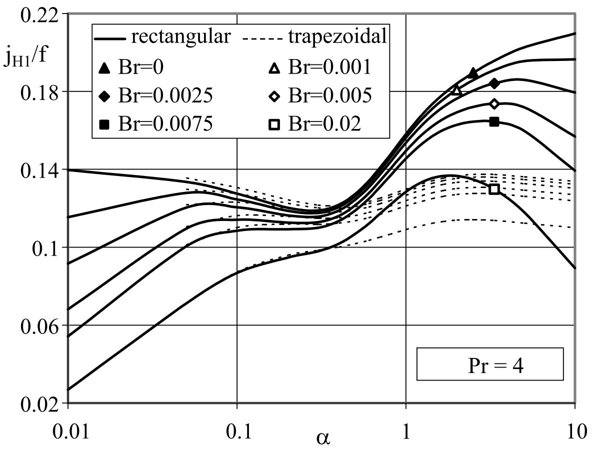
Since the dimensionless quantities j and f are independent of the scale of the geometry (D_h), the area goodness factor j/f for different microchannels represents the influence of the geometric factors on the pressure losses and the heat transfer.

In Fig. 5 the area goodness factor is shown as a function of the aspect ratio α for rectangular and trapezoidal microchannels with four sides heated. It is evident that the rectangular microchannels give, in general, higher values of the area goodness factor; this fact means that the microheat sinks with rectangular microchannels are more compact than those with trapezoidal microchannels for a fixed value of the heat exchanged because they have a lower flow area.

If the viscous dissipation can be neglected ($Br \approx 0$), when rectangular microchannels are employed very high (deep) or very low (shallow) values of the aspect ratio ensure high values of the area goodness factor. On the contrary, for trapezoidal microchannels the j/f factor is a maximum for low aspect ratio (shallow microchannels).



Viscous Dissipation, Figure 5 Area goodness factor j/f as a function of the aspect ratio α for rectangular and trapezoidal microchannels with four sides heated



Viscous Dissipation, Figure 6 Area goodness factor j/f as a function of the aspect ratio α for rectangular and trapezoidal microchannels with three sides heated

It is worth noting from Fig. 5 that when α is low the difference between the trapezoidal and rectangular geometry tends to vanish because the cross-section tends to become similar to parallel plates. It is interesting to note that when the Brinkman number increases the area goodness factor reaches the maximum for intermediate values of the aspect ratio; the viscous effects tend to penalize the performances of the microchannel when very shallow and/or very deep.

These conclusions are confirmed by Fig. 6 for microchannels with three sides heated. In this case for $Br = 0$ the j/f factor is a maximum for high values of the aspect ratio when rectangular microchannels are employed. For microheat sinks with trapezoidal microchannels the j/f factor is always lower than for rectangular microchannels but when the aspect ratio decreases this difference tends to vanish. In addition, Fig. 6 highlights that the dependence of the

j/f factor on the aspect ratio is weak for trapezoidal cross-sections.

Finally, it is important to highlight that the results presented here are valid under the hypothesis of thermophysical properties being independent of temperature. On the contrary the variation with temperature, especially for the fluid viscosity, cannot be ignored in particular for low Reynolds numbers when, for a prescribed wall heat flux, there is a strong temperature rise between the inlet and the outlet of the microchannel. Since the viscosity tends to decrease when the temperature increases, the viscous dissipation effects calculated by using the proposed constant properties model could be overestimated.

Future Directions for Research

The effect of viscous dissipation on convective heat transfer is significant especially for high-velocity flows, highly viscous flows even at moderate velocities, for fluids with a moderate Prandtl number and moderate velocities with small wall-to-fluid temperature difference or with low wall heat fluxes and flowing through microchannels. In this last case, further investigations on the combined effect of the flow work and of the viscous dissipation in microchannels are mandatory by taking into account the temperature variation of the fluid thermophysical properties (especially for the coefficient of thermal expansion and for the viscosity).

Definition

Viscous heating represents the effect of an irreversible process by means of which the work done by a fluid on adjacent layers due to the action of shear forces is transformed into heat.

Overview

In order to study the forced convection of liquids in the laminar regime a common theoretical basis for macro- and microflows can be used; nevertheless, certain effects can be of different importance for microsystems if compared with macrosystems. These effects can be defined as scaling effects with respect to a standard macroanalysis. At the microscale, since different forces have different length dependences, the surface forces (like surface tensions, viscous forces or electrostatic forces) become more important and even dominant as the scale is reduced. Viscous heating, like pressure drop, tends to increase dramatically when the dimensions of microchannels are decreased.

This entry focuses on the role of viscous heating in fluids flowing through microchannels. A criterion will be presented to draw the limit of significance for viscous dissipation effects in microchannel flows. The role of the cross-sectional geometry on viscous dissipation will be highlighted and the minimum Reynolds number for which viscous dissipation effects can no longer be neglected will be calculated as a function of the hydraulic diameter and of the microchannel geometry for different fluids. It will be demonstrated how viscous effects can explain some experimental results on the Poiseuille numbers in microchannels which recently appeared in the open literature.

Basic Methodology

To study laminar flow forced convection in microchannels under the assumptions of steady state axial pressure distribution and fully developed velocity field, the balance of the thermal energy can be written as follows [1] (see ► convective heat transfer in microchannels):

$$\rho c_p v_z \frac{\partial T}{\partial z} = -\nabla \cdot \bar{q} + \beta T v_z \frac{\partial p}{\partial z} + \mu \left[\frac{2}{3} \left(\chi v_z \frac{\partial p}{\partial z} - \beta v_z \frac{\partial T}{\partial z} \right)^2 + \Phi'_{\text{inc}} \right] \quad \text{(for gases)} \tag{1}$$

$$\rho c_p v_z \frac{\partial T}{\partial z} = -\nabla \cdot \bar{q} + \beta T v_z \frac{\partial p}{\partial z} + \mu \Phi'_{\text{inc}} \quad \text{(for liquids)} \tag{2}$$

where Φ'_{inc} for incompressible laminar flows is given by

$$\Phi'_{\text{inc}} = \nabla v_z \cdot \nabla v_z \tag{3}$$

The last term on the right-hand side of Eqs. (1) and (2) represents the work done by the fluid on adjacent layers due to the action of the shear forces (see ► viscous dissipation). This work is entirely transformed into heat by means of an irreversible process and it is responsible for the viscous heating of the fluid.

The integration over the channel cross-section of Eqs. (1) and (2) allows the calculation of the axial distribution of the fluid bulk temperature locally defined as follows:

$$T_b = \frac{1}{W\Omega} \int_{\Omega} v_z T \, \mathrm{d}\Omega \tag{4}$$

in which Ω indicates the area of the channel cross-section and W is the fluid average velocity.

In this entry the effect of the viscous heating in microchannels is highlighted by means of two examples. First of all, a steady-state liquid flow in the laminar regime through a microchannel with an imposed constant linear heat flux

at the walls q'_{w} is considered (H1 boundary condition; see ►convective heat transfer in microchannels). Then, the case of a steady-state liquid flow in the laminar regime through a microchannel with an axially constant outer wall temperature, while the wall heat flux is linearly proportional to the difference between the external temperature and the wall temperature, is considered. This is the case of a microchannel cooled by convection of an external fluid (T3 boundary condition; see ►convective heat transfer in microchannels).

Let us consider the heated microchannel subjected to the H1 boundary condition. By integrating Eq. (2) over the channel cross-sectional area Ω one obtains the following result:

$$D_h^2 \rho c_p W \frac{\mathrm{d}T_b}{\mathrm{d}z} = \frac{q'_{\mathrm{w}}}{\Omega} D_h^2 - 2\mu W^2 f \,\mathrm{Re} \bar{\beta} T_b + 2\mu W^2 f \,\mathrm{Re} \tag{5}$$

where $\bar{\beta}$ is the coefficient of thermal expansion of the fluid calculated at the bulk temperature. The following property of the viscous dissipation term, demonstrated by Morini [2], has been used in order to write Eq. (5):

$$\mu \int_{\Omega} \Phi'_{\mathrm{inc}} \,\mathrm{d}\Omega = 2\mu W^2 f \,\mathrm{Re} \frac{\Omega}{D_h^2} \tag{6}$$

where f is the Fanning friction factor (see ►pressure–driven single-phase liquid flows).

It is interesting to note that, for ideal gases for which $\bar{\beta} = 1/T_b$ the flow work and the viscous dissipation are exactly the same in terms of absolute value and they compensate each to other. For this reason, for ideal gases, the axial variation of the bulk temperature in a channel is independent of viscous heating and flow work even for large values of the Mach number (highly compressible gases).

Equation (6) shows that the viscous dissipation term scales with the internal dimensions of the microchannel. In fact, for a fixed value of the volumetric flow rate ($\dot{V}$) through a microtube with an inner diameter equal to D, the viscous heating generated per unit of length equals the pump power, and it can be written using Eq. (6) as follows:

$$\mu \int_{\Omega} \Phi'_{\mathrm{inc}} \,\mathrm{d}\Omega = \frac{8 f \,\mathrm{Re} \mu \dot{V}^2}{\pi D^4} = \frac{\Delta p \dot{V}}{L} \tag{7}$$

in which Δp is the pressure drop along the microtube and L is the length of the microtube.

By observing Eq. (7) it is evident that the viscous heating and the pressure drop scale with the fourth power of the inner diameter of the channel. This means that viscous heating tends to become very important especially for smaller microchannels.

From the solution of Eq. (5) one can obtain the axial distribution of the bulk temperature along the microchannel. For the H1 boundary condition it is suitable to introduce the following dimensionless quantities (see ►convective heat transfer in microchannels):

$$z^+ = \frac{z}{D_h \mathrm{Re}\,\mathrm{Pr}}; \qquad \Omega^* = \frac{\Omega}{D_h^2}; \qquad \theta_b = k \frac{(T_b - T_{b0})}{q'_{\mathrm{w}}}; \qquad \mathrm{Br} = \frac{\mu W^2}{q'_{\mathrm{w}}} \tag{8}$$

where k is the fluid thermal conductivity and T_{b0} is the value of the bulk temperature at the inlet of the microchannel. Using these dimensionless quantities, Eq. (5) can be written in dimensionless form with the appropriate boundary condition at the entrance:

$$\begin{cases} \dfrac{\mathrm{d}\theta_b}{\mathrm{d}z^+} = \dfrac{1}{\Omega^*} + 2\mathrm{Br} f \,\mathrm{Re} \left[1 - \left(\dfrac{\beta q'_{\mathrm{w}}}{k} \right) \theta_b \right] \\ \theta_b(z^+ = 0) = 0 \end{cases} \tag{9}$$

The analytical solution of this differential problem for a liquid with constant properties is the following:

$$\theta_b(z^+) = \left[\frac{k}{\beta q'_{\mathrm{w}}} \right] \left[1 + \frac{1}{2\Omega^* \mathrm{Br} f \,\mathrm{Re}} \right] \times \left[1 - e^{-2\mathrm{Br} f \,\mathrm{Re} \left(\frac{\beta q'_{\mathrm{w}}}{k} \right) z^+} \right] \tag{10}$$

For an incompressible fluid ($\beta = 0$) the solution of the problem defined by Eq. (9) becomes the following:

$$\theta_b = \frac{1}{\Omega^*} z^+ + 2\mathrm{Br} f \,\mathrm{Re}\, z^+ \tag{11}$$

In the case of a microchannel cooled for convection by an external fluid (T3 boundary condition), the heat flux at the walls can be written as

$$q'_{\mathrm{w}} = -U_{\mathrm{w}} \Gamma \left(T_b - T_{\mathrm{ext}} \right) \tag{12}$$

in which $1/U_w$ is referred to as the wall thermal resistance and Γ the perimeter of the walls.

By combining Eq. (5) with Eq. (12) and introducing the dimensionless quantities

$$z^+ = \frac{z}{D_h \mathrm{Re\,Pr}}; \quad \Omega^* = \frac{\Omega}{D_h^2};$$
$$\Gamma^* = \frac{\Gamma}{D_h}; \quad \theta_b = \frac{(T_b - T_{\mathrm{ext}})}{(T_{b0} - T_{\mathrm{ext}})}; \tag{13}$$
$$R_w = \frac{k}{U_w D_h}; \quad \mathrm{Br} = \frac{\mu W^2}{k\,(T_{b0} - T_{\mathrm{ext}})}$$

where k is the fluid thermal conductivity and R_w is the dimensionless wall thermal resistance, the energy balance equation and its boundary condition in dimensionless form become

$$\begin{cases} \dfrac{\mathrm{d}\theta_b}{\mathrm{d}z^+} = -\dfrac{4}{R_w}\theta_b + 2\mathrm{Br} f\,\mathrm{Re} \\ \qquad \times \left[1 - (T_{b0} - T_{\mathrm{ext}})\,\bar{\beta}\theta_b - T_{\mathrm{ext}}\bar{\beta}\right] \\ \theta_b(z^+ = 0) = 1 \end{cases} \tag{14}$$

The analytical solution of Eq. (14) for a liquid with constant properties is

$$\theta_b(z^+) = \left[1 - \frac{B}{A}\right] e^{-Az^+} + \frac{B}{A}$$
$$\text{with} \quad A = \left[\frac{4}{R_w} + 2\mathrm{Br} f\,\mathrm{Re}\,(T_{b0} - T_{\mathrm{ext}})\,\bar{\beta}\right] \tag{15}$$
$$\text{and} \quad B = 2\mathrm{Br} f\,\mathrm{Re}\left[1 - T_{\mathrm{ext}}\bar{\beta}\right]$$

For an incompressible fluid ($\beta = 0$) the solution of Eq. (14) becomes

$$\theta_b\left(z^+\right) = \left[1 - \frac{\mathrm{Br} f\,\mathrm{Re} R_{\mathrm{w}}}{2}\right] e^{-\frac{4z^+}{R_{\mathrm{w}}}} + \frac{\mathrm{Br} f\,\mathrm{Re} R_{\mathrm{w}}}{2} \tag{16}$$

For an adiabatic microchannel ($R_w = \infty$) in which an incompressible fluid ($\beta = 0$) flows the solution of Eq. (14) becomes

$$\theta_b(z^+) = 2\mathrm{Br} f\,\mathrm{Re}\,z^+ + 1 \tag{17}$$

Examples of Application

The theory developed in the previous section is used to draw the limit of significance of viscous dissipation in heated and adiabatic microchannels.

In particular, in this section a criterion will be stated in order to predict the range of the Brinkman number where the viscous dissipation effect cannot be neglected in the analysis of the fluid flow and heat transfer in microchannels.

Heated Microchannels

If one considers the case of an incompressible liquid flowing through a heated microchannel the axial distribution of the bulk temperature is given by Eq. (11). This equation highlights that the temperature rise along the microchannel is given by two contributions: the heat flux imposed at the walls ($\theta_{b,q}$) and the viscous heating inside the fluid ($\theta_{b,v}$):

$$\theta_b = \frac{1}{\Omega^*} z^+ + 2\mathrm{Br} f\,\mathrm{Re}\,z^+ = \theta_{b,q} + \theta_{b,v} \tag{18}$$

If one considers the ratio between these two contributions, it is possible to demonstrate that this ratio is linked to the Brinkman number and to the Poiseuille number by means of the following relation:

$$\kappa = \frac{\theta_{b,v}}{\theta_{b,q}} = 2\mathrm{Br}\,\Omega^* f\,\mathrm{Re} \tag{19}$$

In order to draw the limit of the significance of the viscous heating in a microchannel, one can impose that this term has to be considered as significant only if this ratio is greater than a fixed value ($\kappa_{\mathrm{lim}} = 1 - 5\%$) [3]; in this manner the following inequality for the Brinkman number can be introduced:

$$\mathrm{Br} > \frac{\kappa_{\mathrm{lim}}}{2\Omega^* f\,\mathrm{Re}} \tag{20}$$

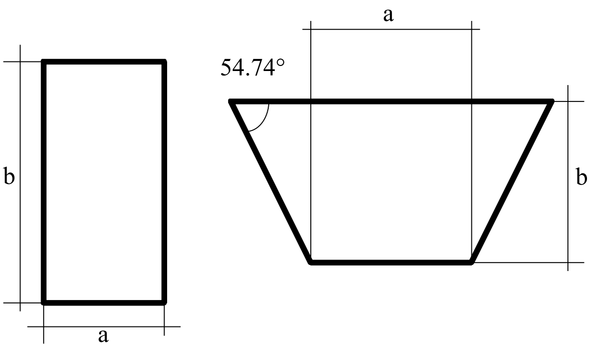
If this inequality holds, the effects of the viscous dissipation cannot be neglected.

For silicon microchannels produced by chemical etching, the shape of the channels depends on a variety of factors such as the crystallographic nature of the silicon used. For example, when an anisotropic KOH etching technique is employed in ⟨100⟩ or ⟨110⟩ silicon, the microchannels have a trapezoidal cross-section (with an apex angle of 54.74° imposed by the crystallographic morphology of the silicon) or a rectangular cross-section respectively. The cross-section is in general characterized by the aspect ratio α defined as the ratio between the height (b) and the minimum width (a) of the channel (see Fig. 1).

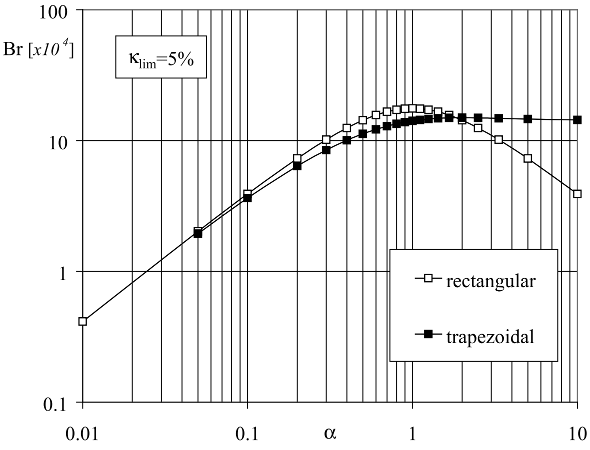
For rectangular and trapezoidal channels the dimensionless area of the cross-section is a function of the aspect ratio (α) and of the apex angle (ϕ); it can be expressed as

$$\Omega^* = \frac{\left[1 + \alpha\left(\frac{1}{\tan\phi} + \frac{1}{\sin\phi}\right)\right]^2}{4\alpha^2\left[\frac{1}{\alpha} + \frac{1}{\tan\phi}\right]} \tag{21}$$

In Fig. 2 the maximum value of the Brinkman number for which the viscous dissipation effects can be neglected for



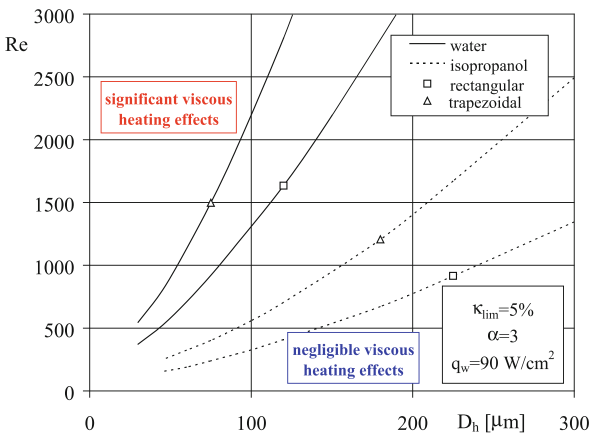
Viscous Heating, Figure 1 Typical cross-section of KOH-etched microchannels



Viscous Heating, Figure 2 Maximum value of the Brinkman number for which viscous dissipation effects can be neglected for trapezoidal ($\phi = 54.74°$) and rectangular ($\phi = 90°$) microchannels as a function of the aspect ratio α

microchannels having trapezoidal ($\phi = 54.74°$) and rectangular ($\phi = 90°$) cross-sections is depicted as a function of the aspect ratio α. A value of κ_{lim} equal to 5% is considered. The results in Fig. 2 show that for shallow microchannels the effects of the viscous dissipation become important for lower Brinkman numbers.

In order to consider the applicability related to microchannels of the proposed criterion, the value of the minimum Reynolds number (linked to the minimum Brinkman number indicated in Eq. (20)) for which κ becomes equal to 5% is computed as a function of the hydraulic diameter for a rectangular microchannel having $\alpha = 3$. In Fig. 3 the minimum Reynolds number is shown for water and isopropanol as working fluids in rectangular and trapezoidal microchannels having an aspect ratio $\alpha = 3$. A constant wall heat flux equal to 90 W/cm^2 is considered. It is evident that the viscous effects are more important for isopropanol than for water because the isopropanol is char-



Viscous Heating, Figure 3 Maximum Reynolds numbers for which the effects of viscous dissipation can be neglected in a heated KOH-etched microchannel with imposed wall heat flux q_W

acterized by a lower value of the specific heat at constant pressure as compared to water; as a consequence, the same viscous heating produces a larger temperature rise in isopropanol than in water. In addition, it is interesting to note that for water the viscous effects have to be considered only for microchannels having a hydraulic diameter less than 100 μm; when the hydraulic diameter decreases the minimum Reynolds number decreases and the viscous effects become important even if the Reynolds numbers are low ($\text{Re} < 500$). In Fig. 3 the role of the cross-sectional shape is highlighted; it can be seen that the viscous effects occur earlier in a rectangular microchannel for a fixed value of the hydraulic diameter and aspect ratio. Figure 3 proves that the viscous effects are typical scaling effects. In fact, they are negligible for high values of the hydraulic diameter but become more important when hydraulic diameters less than 100 – 300 μm are considered.

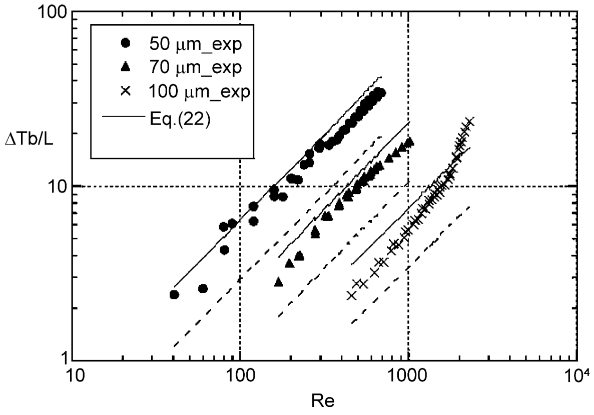
V

Adiabatic Microchannels

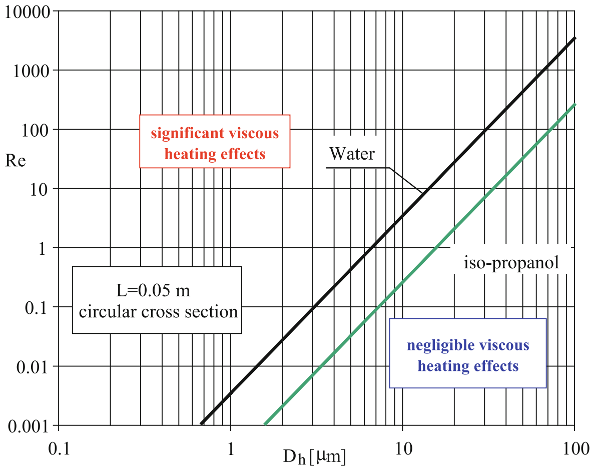
For an adiabatic microchannel in which an incompressible liquid flows, the axial temperature rise due to viscous heating can be computed by means of Eq. (17). For a microchannel with a length equal to L, the axial temperature gradient results from Eq. (17) in which the definitions reported in Eq. (13) are used:

$$\frac{\partial T_b}{\partial z} \cong \frac{\Delta T_b}{L} \cong 2\frac{\mu W}{\rho c_p D_h^2} f \,\text{Re} \tag{22}$$

In order to validate this result the experimental data of Celata et al. [4] are used. Celata et al. measured the temperature difference between inlet and outlet of a smooth



Viscous Heating, Figure 4 Gradient of viscous heating ($\Delta T_b/L$) along adiabatic microtubes versus Reynolds number; comparison of measurements (exp) and the theory for incompressible ($\beta = 0$) laminar flows (Eq. (22))



Viscous Heating, Figure 5 Reynolds numbers for which the temperature rise due to viscous heating along an adiabatic circular microchannel 5 cm long is equal to 1 K as a function of the hydraulic diameter

capillary tubes ($f\,\mathrm{Re} = 16$) of fused silica with hydraulic diameters equal to 100, 70 and 50 μm through which water is circulated at different Reynolds numbers in the laminar regime. The comparison between the prediction of Eq. (22) and the experimental data is shown in Fig. 4, and the agreement between the model and the measurements is good. The agreement improves for larger Reynolds numbers and smaller diameters; this fact is due to the smaller temperature rise at lower Reynolds number and larger diameters.

Considering Eq. (22), it is possible to note that, for two different fluids, c and d, and for a fixed value of the Reynolds number, hydraulic diameter and cross-sectional geometry, the temperature gradient ratio is related to the following ratio of the fluid thermophysical properties:

$$\frac{\left(\frac{\mathrm{d}T_b}{\mathrm{d}z}\right)_c}{\left(\frac{\mathrm{d}T_b}{\mathrm{d}z}\right)_d} = \left(\frac{\nu_c}{\nu_d}\right)^2 \left(\frac{c_{pd}}{c_{pc}}\right) \tag{23}$$

The temperature gradient due to the viscous heating is larger for fluids having a large value of kinematic viscosity and a low value of specific heat. For example, for isopropanol and water this ratio is equal to 13.26 at 298 K; for methanol and water this ratio is equal to 2.32 at 298 K. It is interesting to note that for water and air the ratio quoted in Eq. (23) is equal to 10^3 at 298 K; this means that the effects of viscous dissipation could be very strong for air. However, the influence of the compressibility is very important for gases flowing through microchannels and β cannot be neglected; the gas expansion in the flow direction causes a decrease of the temperature, which contrasts the effects of viscous heating.

It is possible to suggest a criterion to establish when viscous dissipation effects cannot be ignored in an adiabatic microchannel. Considering that for water and isopropanol the dynamic viscosity decreases by about 20–25% per 10 K one can assume as reference temperature rise an increase of 1 K of the bulk temperature between the inlet and outlet of a microchannel [2].

When the bulk temperature increase along the microchannel is greater than 1 K the effect of the viscous dissipation cannot be neglected. This means that the following inequality must be satisfied in order to neglect the viscous heating in adiabatic microchannels:

$$\begin{aligned}(T_{be} - T_{b0}) &= (T_{b0} - T_{\mathrm{ext}})\left(\theta_b\left(z_e^+\right) - 1\right)\\ &= 2\frac{Br}{\mathrm{Re\,Pr}}\frac{L}{D_h} f\,\mathrm{Re}\,(T_{b0} - T_{\mathrm{ext}}) < 1\\ \text{with}\quad z_e^+ &= \frac{L}{D_h \mathrm{RePr}}\end{aligned} \tag{24}$$

where L is the microchannel length, T_{be} is the fluid temperature at the exit of the microchannel, θ_b and Br are as defined in Eq. (13).

Equation (24) can be adopted as a criterion to predict the upper limit of significance of viscous dissipation in a microchannel. Equation (24) allows, for a fixed microchannel geometry and hydraulic diameter, the calculation of the values of the Reynolds number for which the temperature rise between inlet and outlet is equal to or greater than 1 K.

Figure 5 shows the Reynolds number for which the temperature rise, between inlet and outlet of a microtube 5 cm long, becomes equal to 1 K as a function of the hydraulic

diameter of the microchannel, for both water and isopropanol flows.

Finally, it must be noted that Eq. (17) can be used to determine experimentally the value assumed by the friction factor in an adiabatic microchannel for incompressible liquids:

$$f = \frac{\mathrm{Pr}}{\mathrm{Br}} \frac{D_h}{L} \left(\theta_b(z_e^+) - 1\right) \tag{25}$$

The friction factor can thus be determined without measuring the pressure drop along the microchannel but by means of temperature and flow rate measurements. This kind of measurement is unsuitable when macrochannels are tested. For this reason Eq. (25) can be considered as an example of the role of scaling effects and to suggest new measurement procedures at the microscale. This relation has been used by Celata et al. [4] in order to determine the friction factor in microchannels. In addition, since Eq. (25) is valid only in the laminar regime, one can use it to individuate the laminar-to-turbulent transition in microchannels. This has been experimentally demonstrated by Celata et al. [4] and Rands et al. [5].

Rearranging Eq. (22) and using the following definition of the Eckert number:

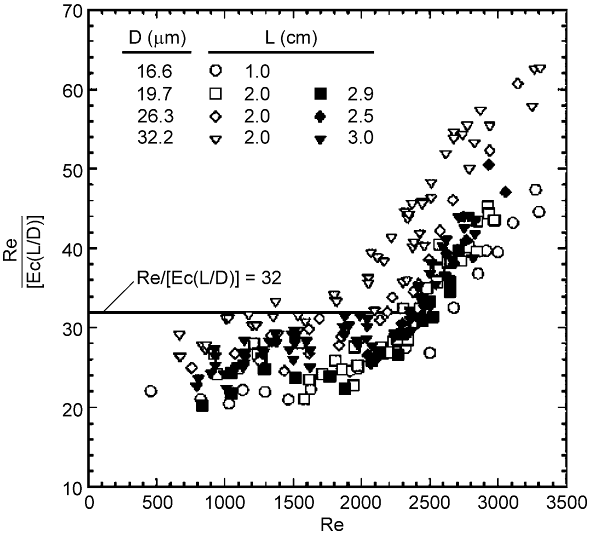
$$\mathrm{Ec} = \frac{W^2}{c_p \Delta T_b} \tag{26}$$

it can be demonstrated that for an incompressible liquid through an adiabatic microchannel the following equation holds in the laminar regime:

$$\frac{\mathrm{Re}\, D_h}{\mathrm{Ec}\, L} = 2 f\, \mathrm{Re} \tag{27}$$

Rands et al. [5] experimentally tested this equation for circular microtubes ($f\,\mathrm{Re} = 16$) having diameters ranging between 16.6 and 32.2 μm and with lengths between 1 and 3 cm.

In Fig. 6 the experimental results obtained by Rands et al. [5] are compared with Eq. (27); it is evident that the comparison between Eq. (27) and the experimental results allows one to individuate the laminar-to-turbulent transition in microchannels without the need to use pressure gauges.



Viscous Heating, Figure 6 Comparison between experimental results of Rands et al. [5] and Eq. (27) for incompressible laminar flows

Future Directions for Research

The effect of the viscous heating of fluids in microchannels is significant especially for hydraulic diameters less than 200 μm. In this case, further investigations on the combined effect of the flow work and of the viscous dissipation in microchannels are mandatory by taking into account the temperature variation of the fluid thermophysical properties (especially the coefficient of thermal expansion and the viscosity).

Definition

In the context of microfluidics and nanofluidics, visualization implies the determination of fluid velocity in small scale internal flows. Visualization requires an optically detectable fluid marker that does not alter the local fluid velocity of interest. A variety of visualization methods have been developed for small scale flows, many of which were derived from methods originally developed for macroscale flows. Molecular tagging describes one class of methods that involve molecules being rendered optically differentiable from the bulk fluid to serve as optically detectable fluid markers. The molecular dimensions of these fluid markers make them well suited to small scale flows. Molecular tagging is commonly achieved by select exposure to light, although the specific photochemical mechanisms vary over the four techniques described here.

Overview

Flow visualization has a long history. A well-known early flow visualization experiment is that of Reynolds in 1883, who studied the transition to turbulence in a pipe flow by observing the transport of an injected dye. Although many flow visualization methods have evolved since, all share a fundamental objective: to alter the fluid such that the fluid transport may be observed, yet not alter the fluid motion. The latter half of this objective is very difficult to achieve in that it requires the method to be totally non-intrusive. Instead, the researcher must either demonstrate that the alterations brought about by the marker are negligible, or be able to model the alterations such that the velocity of the undisturbed flow may be determined.

Visualization has played a central role in the development of the field of microfluidics and associated applications. It is both a natural desire, and highly informative to 'see' what is going on inside these small scale systems. The inherent scale of these systems results in significant deviations from macroscale fluid behavior, most notably due to an increase in the role of surface effects and diffusive transport of mass, momentum and energy. Unique micro- and nanoscale transport phenomena present many opportunities for advanced functionality as exploited by the many applications described in this encyclopedia and elsewhere. The scale of these systems, however, also presents some unique challenges with respect to visualization. Most notably, on the microscale the non-intrusive requirement precludes the use of many techniques commonly applied to macroscale flows, such as hot-wire anemometry and the injection of dye by mechanical means. In addition it is not possible to observe the phenomena without the use of a microscope. Several visualization techniques have, however, been successfully applied to microscale flows. Like much of the research in microfluidics and nanofluidics, many proof-of-concept contributions have appeared in the 1990s, and subsequent advancement has been rapid. Most visualization techniques applied to microstructures may be conveniently divided into two categories: particle based methods and scalar based methods [1].

Particle based visualization methods have been well developed for macroscale flows and popular for many years. In these methods, the motion of the bulk fluid is inferred from that of observed marker particles. Different methods of acquiring and analyzing particle transport data have evolved including, briefly, laser Doppler *velocimetry*, particle streak velocimetry, and particle image velocimetry. The latter includes particle tracking velocimetry and pattern matching velocimetry algorithm methodologies. Although not the focus of this entry, these particle based methods have been successfully applied to microscale flows and highly instrumental in microsystem development. Detailed descriptions of these methods are available in this encyclopedia and elsewhere.

In scalar based visualization methods, the motion of the bulk fluid is inferred from the observed velocity of a con-

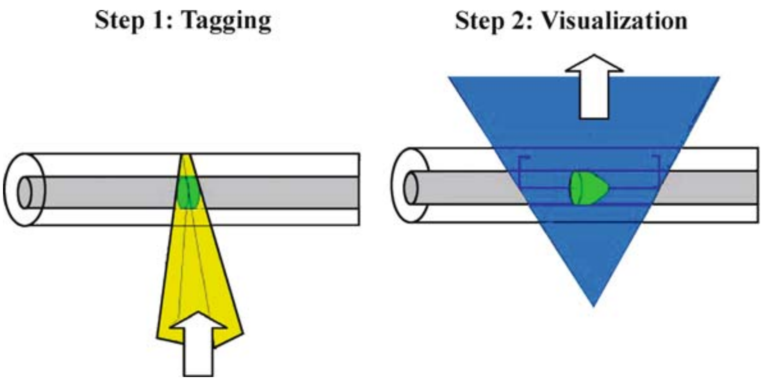
served scalar, quite often a dye. Reynolds' historic work fits in this category as do many other visualization methods developed since. The key distinction between scalar and particle based methods is that particle based methods track individual particles whereas scalar based methods track a tagged solute concentration. In the limit where particle sizes approach molecular dimensions, and/or single molecule tracking is involved, this particle/scalar distinction vanishes. Some studies in this regime are discussed under key research findings and future research sections. Commonly employed molecular tagging methods, however, fall under the classification of scalar based visualization. It is the observed transport of a concentration of *tagged* molecules that provides the basis for the determination of fluid velocity.

A schematic illustrating the generic molecular tagging approach is given in Fig. 1. The microchannel, in this case a circular capillary, initially contains a fluid with uniform optical/fluorescent properties. Molecular tagging is most commonly applied to liquid aqueous flows, however, organic solvents and gases have been used as well. In the first step, a portion of the fluid is differentiated from the bulk fluid, or *tagged*, through an interaction with light, commonly from a laser. The specific photochemical mechanisms that facilitate the molecular tagging vary over the four techniques described here, namely: photobleached fluorescence, photochromic reaction, phosphorescence, and caged fluorescence. For the tagging light source, lasers are often employed to achieve a high intensity, wavelength specific, tightly focused light exposure. With the setup shown in the schematic, the molecules are tagged in a cross-sectional volume by a focused sheet of light oriented perpendicular to the channel (this is a common configuration, although point-based molecular tagging has also been demonstrated). The sheet of tagged molecules is deformed into a bowl shape, characteristic of pressure-driven flow in a circular channel. The second, visualization, step involves imaging the transport of the observed scalar and interpreting the results. The visualization is commonly achieved with a microscope system that delivers/gathers light from the microchannel as illustrated in the figure. The transport of the concentration of tagged molecules is imaged through the microscope onto a CCD camera. The resulting image sequence is then processed and analyzed numerically to determine the fluid velocity.

The channel is filled with an aqueous solution containing caged fluorescent dye (which is non-fluorescent). A cross-sectional *sheet* or *band* of the solution is exposed to a brief, intense pulse of ultraviolet light. This exposure breaks the caging groups in the band of fluid and fluorophores are released. These fluorophores are continuously excited by light from the microscope (blue) and the resulting fluorescent emission (green) is imaged through the microscope onto a CCD camera. An image sequence of the transport of the fluorescent band of dye is then analyzed to determine the bulk liquid velocity in the channel.

Flows in micro- and nanochannels are generally laminar and driven electrokinetically, as in electroosmotic flow, by pressure, or by a combination of the two. The pressure source may be external to the microfluidic network, or internally induced via capillary pressure, valving, or nonuniformities arising from electrokinetic effects. Central to electrokinetic effects is the electrical double layer, or EDL, that results from the non-uniform distribution of electrical charges near phase boundaries. Electrokinetically-driven flow, often called electroosmotic flow, results from the response of liquid ions in the electrical double layer to an axially applied electric field. The electric field may be applied via external electrodes in fluid reservoirs, or through embedded electrodes. The nature of electroosmotic flow is compared to that of pressure-driven flow in the image sequences shown in Fig. 2. The images were obtained using a caged fluorescence molecular tagging method (details described later). The transport of the concentration of tagged molecules illustrates the plug-like velocity profile characteristic of electroosmotic flows in microchannels. The velocity profile appears flat because the flow driving force is generated in the electrical double layer which is typically on the order of 10 nm and thus a very thin layer relative to the diameter of the microchannel on the order of 100 μm. In contrast, the transport of tagged molecules in the pressure driven flow reflects the familiar parabolic velocity profile expected from classical theory. Both pressure-driven and electroosmotic flow present unique challenges and advantages with respect to molecular tagging. The plug-like nature of electroosmotic flows, results in reduced dispersion (or blurring) of the tagged solute. This characteristic of electroosmotic flows has long been exploited in the area of capillary electrophoresis. However, the electrophoretic velocity of the tagged solute (if charged) in response to the applied electric field can bias the measurement of the bulk fluid velocity, and must be taken into account. For pressure-driven flow, electrophoretic effects do not play a role assuming there is no externally applied electric field, and streaming potential is not significant. However, the cross-sectional velocity gradients characteristic of pressure-driven flows result in hydrodynamic dispersion or blurring of the tagged solute resulting in a reduced useful lifetime and reduced resolution, particularly near the channel wall.

The processing and interpretation of a sequence of images documenting the observed transport of a tagged solute involves several considerations. In most cases the desired output is the fluid velocity, exhibiting a spatial resolution



Visualization Based on Molecular Tagging Methods, Figure 1 Schematic illustrating typical molecular tagging methodology as applied to microchannel flow visualization. First, a small cross-stream section of molecules is *tagged* such that they become optically detectable. This step is typically accomplished with intensely focused laser light. Second, the transport of the tagged molecules is recorded, typically using fluorescence video microscopy

as high as possible. Although the fluid velocity is desired, it is the transport of a conserved scalar, the tagged solute concentration that is imaged. This transport, in general, is modeled by the species conservation equation for a dilute solute as follows [2],

$$\frac{\partial c_i}{\partial t} + \boldsymbol{u} \cdot (\nabla c_i) = D_i \nabla^2 c_i + \frac{D_i z_i e}{kT} \nabla \cdot (c_i \nabla \Psi) + R_i \quad (1)$$

where c is the concentration of the tagged solute, $\boldsymbol{u}$ is the bulk fluid velocity, D is the diffusion coefficient, z is the valence charge of the solute, Ψ is the electric potential, R is the rate of generation of the solute, subscript i indicates a quantity specific to the solute species, and other variables/symbols have their usual meanings. For fully developed flow in the x-direction with only an axially applied electric field (i. e., thin electrical double layer limit), Eq. (1) may be recast as,

$$\frac{\partial c_i}{\partial t} + \left(u_x + u_{\text{ph_}x}\right) \cdot (\nabla c_i) = D_i \nabla^2 c_i + R_i \quad (2)$$

where $u_{\text{ph_}x}$ indicates the axial velocity of the solute due to electrophoretic response to the applied field. This velocity is given by,

$$u_{\text{ph_}x} = \frac{D_i z_i e}{kT} \left(-\frac{\partial \Psi}{\partial x} \right) = \nu_{\text{ph}} (E_x) \quad (3)$$

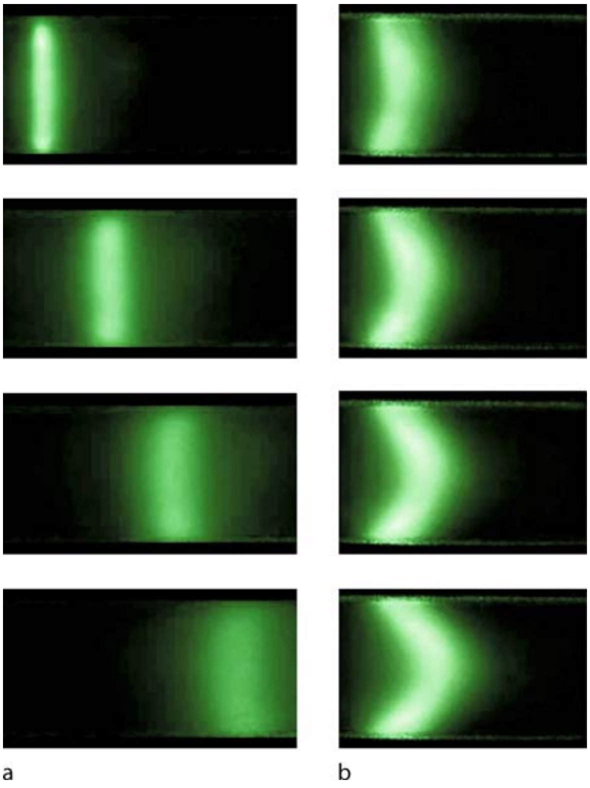
Essentially, Eqs. (1–3) indicate that in addition to bulk fluid velocity, $\boldsymbol{u}$ (which is the desired output), the imaged concentration is also a product of transport by diffusion and electrophoretic motion, and the rate of generation of the tagged molecules. Thus the visualization problem is somewhat the inverse of the conventional computational modeling problem where the evolution of the concentration field is calculated from a known bulk velocity field. In contrast, the bulk velocity field is calculated from the known evolution of the concentration field when interpreting image sequences for visualization purposes. Methods to perform this calculation are discussed in the next section, following a description of four molecular tagging strategies.

Basic Methodology

The basic methodology behind molecular tagging based visualization is illustrated in Fig. 1. In the first step, a portion of the fluid is differentiated from the bulk fluid, or *tagged*, through an interaction with light. In the second step, the transport of the tagged solute concentration is imaged and interpreted to determine the fluid velocity. Provided below are the details of four molecular tagging approaches, and a description of image processing and interpretation procedures.

Photobleached Fluorescence Tagging

Fluorescence is the process by which molecules that are excited by electromagnetic radiation almost immediately emit a photon. It occurs in molecules termed fluorophores, typically polyaromatic hydrocarbons, in a multi-step process. A photon is absorbed by the fluorophore, elevating it to an excited state for a short period (typically 1 – 10 ns) and then the fluorophore releases a photon. The released photon is of lower energy than the absorbed photon due to energy dissipated in the excited state. This energy loss corresponds to a shift in wavelength between the absorbed and emitted light, termed the Stokes shift, and facilitates the filtering out of all excitation light from fluorescence emission and is the basis for fluorescence microscopy. For example, fluorescein dye molecules have an absorption



Visualization Based on Molecular Tagging Methods, Figure 2 Visualization of electroosmotic flow (**a**), as compared to pressure-driven flow (**b**), using caged-dye based molecular tagging method. The microchannel was circular in cross-section and 200 μm in diameter. Both the plug-like velocity profile characteristic of electroosmotic flows, and the parabolic velocity profile characteristic of pressure-driven flows are apparent. Adapted from [1] with permission

maximum around $\lambda = 490$ nm and an emission maximum at approximately $\lambda = 513$ nm. Thus if a microfluidic channel is uniformly illuminated with a single-line argon laser at $\lambda = 488$ nm, and a fluorescence microscope filters out all light below $\lambda < 500$ nm, only fluorescent emission from fluorescein molecules will be imaged by the camera. The excited lifetime of fluorescence is too short to facilitate a molecular tagging based visualization strategy (i. e., the flow-wise displacement between excitation and emission would be too small to measure for most flowrates of interest). However, photobleaching of fluorescence does enable molecular tagging based visualization.

Photobleaching of fluorophores is a process by which exposure to excitation light results in chemical alterations rendering the molecule non-fluorescent. Burning out a light bulb is analogous to photobleaching a fluorophore. The rate of photobleaching depends on the photon flux, and photobleaching is typically permanent in aqueous solutions. A common problem in biology experiments, photobleaching can be used to good effect as a molecular tagging strategy. With this tagging method, the fluid is first uniformly seeded with a dilute concentration of fluorescent dye. The molecular tagging step (as shown in Fig. 1) is achieved with a light source close to the absorption maximum of the dye. The intensity and duration of exposure must be sufficient to induce significant local photobleaching. The visualization step involves fluorescence microscopy, where the *tagged* solute is differentiated from the rest of the fluid as it is non-fluorescent. An argon laser is commonly employed in combination with fluorescein dye to achieve the photobleaching [3], however another method employed the reflective optical properties of a gaseous bubble in the microchannel to locally focus flood illumination and achieve local photobleaching without a secondary light source [4]. An image of a photobleached fluorescence tagged flow marker is shown in Fig. 3 along with an electroosmotic velocity profile determined using photobleached fluorescence. The velocity profile exhibits the plug-like shape, characteristic of electroosmotic flows, with resolution extending to 5 μm from each wall.

An advantage of photobleached fluorescence tagging is that visible light and standard, relatively inexpensive, fluorescent dyes can be employed. A disadvantage of this technique is that the signal-to-noise ratio (SNR) that defines image contrast is as much as an order of magnitude [3] lower than caged fluorescence tagging (discussed below). Furthermore, because it is the *unmarked* fluid in the chan-

nel that is fluorescing, out-of-plane velocity gradients can occlude the photobleached section. For this reason, photobleached fluorescence tagging is suited more to electroosmotic flows than to pressure-driven flows.

Photochromic Reaction Tagging

Photochromic reactions induce a change in the absorption spectrum of a solution. This change is observed as a change in the colour of a solution. The tagging process can occur on the order of nanoseconds, however, the colour change, typically from clear to blue, can persist for seconds to minutes. Photochromic reaction tagging is induced by exposure of the solution to ultraviolet light. Although some water-soluble photochromic dyes are now available, many photochromic dyes require the use of organic solvents such as kerosene and ethanol, which limit their usefulness in microfluidic applications that primarily involve aqueous solutions. Another disadvantage of this tagging method is that the image is produced by a change in absorbance which is inherently less sensitive than an image produced by emitted light against a black background as is the case in fluorescence and phosphorescence. None the less, this molecular tagging method has been successfully applied both in macroscale flows and microscale flows.

Phosphorescence Tagging

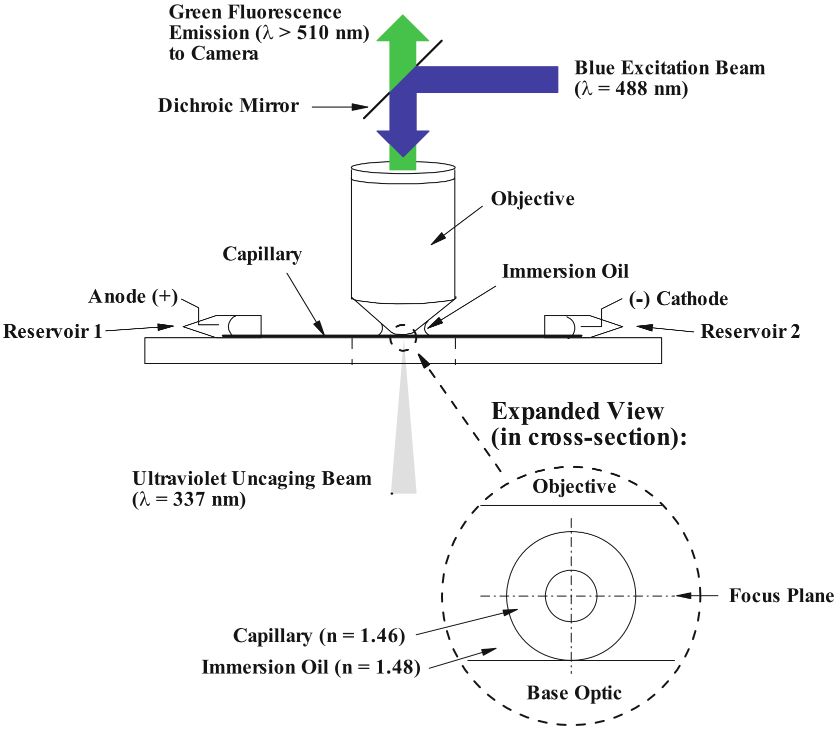
Phosphorescence is the process by which molecules, excited by electromagnetic radiation, become excited to a higher level and emit energy in the form of light as they return to their unexcited state. The central difference between fluorescence and phosphorescence is the length of time between excitation and emission. Phosphorescence emission lifetimes can be as long as several milliseconds ($\sim$ ms), which is much longer than fluorescence ($\sim$ ns), but much shorter than colour changes in photochromic dyes ($\sim$ s). Thus unlike fluorescence, phosphorescent molecules are suitable for molecular tagging applications where the tracer lifetime ($\sim$ ms) is long enough relative to the flow convection timescale to produce a quantifiable displacement. In other words, phosphorescence itself can be used as a molecular tagging mechanism, without an associated bleaching or caging strategy.

A distinct advantage of phosphorescence based molecular tagging is that only a single light source, that required for excitation, is needed to visualize the flow. Typically a UV laser is used. Traditional phosphorescent molecules suffered from O_2 and H_2O quenching during their excited states, however, so-called phosphorescent supramolecules have been developed more recently that resist quenching. These compounds have been applied to both macro- and microscale flows. For microflows, the emission lifetime on the order of milliseconds restricts their applicability to relatively high-speed microflows. In addition, water-soluble phosphorescent supramolecules require a significant concentration of alcohol ($c \sim 100$ mM or higher) in solution to perform effectively. Thus applicability of this method to study electrokinetic phenomena is limited.

Caged Fluorescence Tagging

Caged fluorescent dyes are fluorophores with additional chemical groups that render the fluorophore nonfluorescent. A caged fluorophore may be *uncaged* by exposure to certain wavelengths of light that break the bonds attaching the caging groups. The original fluorophore is recovered through this process, termed photolysis, and may be tracked indefinitely through fluorescence microscopy. With this tagging method, the fluid is first uniformly seeded with a dilute concentration of caged fluorescent dye. A range of caged dyes are available commercially (Invitrogen Corp.). The molecular tagging step (as illustrated in Fig. 1) is achieved with a light source close to the absorption maximum of the caged dye, (which is distinct from the absorption maximum of the fluorophore) normally in the ultraviolet range ($\lambda < 360$). Once uncaged, the fluorophore requires excitation in the appropriate wavelength range, which is on the order of $\lambda = 490$ nm for fluorescein. Standard fluorescence microscopy equipment is typically sufficient to image the uncaged dye transport. The images shown in Fig. 2 were obtained using fluorescence video microscopy following caged dye based molecular tagging. A schematic of the experimental setup employed is given in Fig. 4. In the case shown, circular cross-section capillaries were used in conjunction with optical immersion oil and an oil immersion objective. The immersion system ensures minimal signal loss and prevents optical distortion due to the capillary wall (the latter is not an issue with chip-based microchannels).

The most critical time scale in caged fluorescence based molecular tagging is the time delay between absorption of the photolysis radiation (untagging light exposure), and a significant release of fluorophore. Several studies have investigated this rate of release. Some fluorescence has been detected only 1 μs [5] after photolysis radiation exposure, more significant release on the order of 10 ms, and gradual increase continuing up to 0.5 s. In general, the time delay is a function of the intensity of the untagging light exposure, the concentration of the caged dye, the sensitivity of the detector employed, and likely other factors including the pH and temperature of the solution. In the context of molecular tagging, this time-delayed release has two ramifications: it imposes a limit on the maxi-



Visualization Based on Molecular Tagging Methods, Figure 4 Schematic of typical experimental setup employed for caged-dye based visualization in capillaries. Optical immersion oil setup ensures minimal signal loss and prevents optical distortion at the capillary wall (the latter is not an issue with chip-based microchannels). Adapted from [6] with permission

mum flow velocity measurable over a given displacement, and the rate of generation term, R, in Eq. (1) becomes finite and thus requires consideration in the image processing/interpretation.

Since uncaged fluorescent dye is detectable at relatively low concentrations, this molecular tagging technique is applicable to electrokinetic flows. Applying caged fluorescence based molecular tagging to electrokinetic flows, however, requires knowledge of the electrophoretic velocity of the dye. As shown in Eq. (2), the observed velocity of the tagged solute is in fact a result of the desired bulk fluid velocity, as well as the electrophoretic velocity if the uncaged dye is charged. In the extreme case where the electrophoretic mobility of the tagged solute is equal to the electroosmotic mobility, the tagged solute will remain stationary regardless of bulk fluid motion. In general however, if the microchannel section of interest is straight and of constant cross-section, the electrophoretic dye velocity may be calculated directly from dye property data and boundary conditions. More involved methods have been developed in order to additionally account for Joule heating induced fluid temperature rise on this calculation [6]. It has also been reported that the adsorption of caged dye onto polymer microchannel walls can alter the surface properties, and thus applicability of caged fluorescence based molecular tagging to electrokinetic flows in polymer based microchannels may be limited.

Caged fluorescence tagging is generally limited to small scale visualization experiments as the cost of caged dyes is relatively high (portions on the order of milligrams are commonly valued on the order of hundreds of US dollars). Another consideration is that the signal strength is generally low (depending on uncaging intensity, untagged volume, dye concentration etc.). Despite some disadvantages however, caged dye based molecular tagging has been relatively popular, and successfully applied in a wide variety of microscale flow visualization efforts. Some of these works are highlighted in the key research findings section here, and a detailed listing is provided elsewhere [1].

V

Determining Velocity from the Image Data

The first step in interpreting the image data is image processing. Image processing is required to both remove any non-uniformities present in the imaging system, and to convert fluorescence or absorbance levels to concentration.

At the minimum this process involves dark-field subtraction and bright-field normalization. Multiple texts on digital image processing are available.

After processing, intensity levels in the image set may be interpreted directly as concentration, and thus the image set forms a sequence of snap-shot solutions to the transport equation described earlier, Eqs. (1–3). The general process of extracting the bulk fluid velocity, $\boldsymbol{u}$, from the species transport equation has been studied extensively and termed Scalar Image Velocimetry (SIV) [7]. A full SIV formulation can be quite involved. For the specific case illustrated in Fig. 1, where a cross-sectional band of molecules are tagged in a straight channel of uniform cross-section, a much simplified SIV technique, such as the one illustrated in Fig. 5, can be effective. In short, the strategy involves choosing axial points of maximum concentration as marker points, and tracking the motion of these marker points over time (i. e., through the image sequence) to determine the cross-stream velocity profile. The axial maximum concentration points are chosen as their axial position is less effected by diffusion and any rate of generation or photobleaching of tagged molecules. As shown in the figure, the axial maximum concentration points form a cross-stream profile at each time-step. The axial displacement of this profile, divided by the time delay between images provides a cross-sectional velocity profile, $\boldsymbol{u}$. Although this method has limitations, it is relatively straightforward to implement computationally and has provided reliable results both for pressure-driven and electroosmotic flows. Some key research findings are summarized in the next section.

Key Research Findings

The limited space available here does not allow for comprehensive review of the multitude of important research contributions, particularly since the late 1990s, in the area of molecular tagging based visualization of small scale flows. For a comprehensive review, the reader is referred to a recent review paper [1] and the references therein. Below, a sampling of some early and influential papers in this area are discussed.

The term molecular tagging velocimetry first became popular in connection to phosphorescence tagging methods [8]. Originally employed in macroscale flow visualization studies [8], so-called phosphorescent supramolecules have since been applied to visualization of relatively fast flows in microtubes.

In 1998, Paul et al. [9] applied caged fluorescence tagging to visualize flows in capillaries. The importance of that contribution is evidenced by a long citation record. This technique has been adapted by several groups, and applied to study flows in microchannel bends, the effect of non-uniform zeta potential, flows in plastic microchannels, Joule heating effects (both on the determination of electrophoretic velocity and on the flow), and many others as described in Ref. [1] and references therein. Shelby and Chiu [5] extended the use of caged fluorescence tagging in microsystems to high speed pressure-driven flows using extremely sensitive single point detection.

Mosier et al. [3] applied photobleached fluorescence tagging to study both electrokinetic and pressure-driven flows in rectangular microchannels. High molecular weight fluorescent conjugates were used to decrease diffusive effects (a diffusion coefficient four orders of magnitude below that of fluorescein). An argon laser was employed to achieve the photobleaching while a fluorescence microscope facilitated the visualization. A niche flow marking technique requiring only flood illumination was later developed using the reflective optical properties of a microchannel-entrapped bubble [4].

Future Directions for Research

The application of molecular tagging based visualization to nanoscale flows is an exciting research direction. The molecular dimensions of these probes make them well suited to these geometries, however, several challenges exist. Most notably, resolving nanoscale features with visible light presents a fundamental challenge due to the inherent wavelength of visible light. Along similar lines it is expected that as nanoscale based flow visualization methods are developed, traditional distinctions between scalar based and particle based methods will vanish. Although nanoscale velocity gradients have not yet been resolved, depth-wise averaging of fluorescence signal over nanoscale depths is one strategy that has been successfully employed recently in nanoscale electrophoresis applications. Another future research avenue is the improvement of molecular tagging probe chemistries and invention of new molecular tagging strategies. A wide variety of probes are produced in response to demand from biological research and molecular probes with improved functionality for visualization purposes may be a useful byproduct of this demand. Lastly, molecular tagging based velocimetry could play an interesting role in the rapidly emerging field of optofluidics, the marriage of optics and fluidics.

Direct bonding; Fusion bonding

Definition

Wafer bonding is a process by which two mirror-polished wafers of any materials adhere to each other at room temperature without the application of any macroscopic gluing layer or external force. The bonding is achieved through van der Waals force. Wafer bonding achieved at room temperature is usually relatively weak compared to metallically, covalently or ionically bonded solids. Therefore, for many applications the room temperature bonded wafers have to undergo a heat treatment to strengthen the bonds across the interface.

Overview

It has long been known that mirror-polished surfaces, when in direct contact, adhere to each other by capillary force, or electrostatic force or van der Waals force. In the absence of liquid or electrical charge at the mirror surfaces, the van der Waals force is the primary force to cause adhesion of two mirror-polished surfaces. The van der Waals force is an extremely short-ranged attractive force between two polar molecules. However, the force can be *long ranged* if there are water molecules participating the process, because the hydrogen atoms in water molecules can bridge with other molecules to form *long-ranged* hydrogen bonds instead of direct bonds between the solid atoms [1]. In the example of silicon wafer bonding, most silicon wafers are covered with a thin native oxide (~ 2 nm) or purposely grown thermal oxide which have typically a monolayer or two of water molecules absorbed on OH groups associated with the oxide. At room temperature, silicon wafers may be bonded by relatively weak *hydrogen bridges*. A subsequent heat treatment can turn the weak hydrogen bonds to strong covalent bonds. For a hydrophobic surface where the thin oxide has been removed by dipping into HF, the process is expressed as Eq. (1). For a hydrophilic surface where there is a thin oxide layer, the process is expressed as Eq. (2).

Hydrophobic surface:

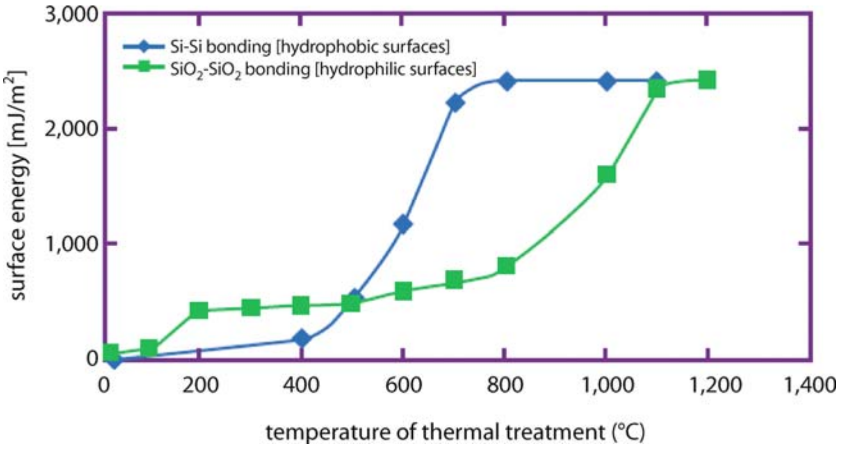
$$\mathrm{Si-H+H-Si \Rightarrow Si-Si+H_2} \quad (1)$$

Hydrophilic surface:

$$\mathrm{Si-OH+HO-Si \Rightarrow Si-O-Si+H_2O} \quad (2)$$

In both cases strong covalent bonds are formed after heat treatment. For a hydrophobic surface, the process starts at about 500 °C, while for a hydrophilic surface it is about 120 °C [1]. Typical change of surface energy with heat treatment temperature is shown in Fig. 1. Though they started differently as temperature rises, both hydrophobic and hydrophilic surfaces gain high surface energy at high temperature. The full covalent bond formation is accomplished at temperatures from 800 to 1200 °C. The bonds formed at such temperatures are as strong as those of a crystalline solid.

The first systematic investigation of room temperature adhesion between two optically polished glass plates was done by Lord Rayleigh in 1936. Later, the *anodic bonding* technique was developed for semiconductor wafer bonding with glasses and metals. Direct bonding of silicon wafers was first reported in 1986 [2]. In the same year, silicon wafer bonding with an oxide intermediate layer was also reported, which opened a new route for manufacturing silicon-on-insulator (SOI) wafers [3]. Semiconductor devices built on a SOI substrate were favoured because of their high resistance against the undesirable side effect of radiation-induced electron–hole pairs for application in outer space. The original driving force of *radiation hardness* behind SOI development, however, was dwarfed by



Wafer Bonding, Figure 1 Evolution of surface energy with temperature for hydrophobic and hydrophilic surfaces

its great commercial potential in integrated circuits (IC) manufacturing. ICs built on SOI substrates allow operation at lower voltage and higher packing density, as well as simultaneous use of low and high voltage on one chip. SOI technology has become the mainstream technology for the next generation of ICs [4]. Prior to the advent of silicon direct bonding, SOI wafers were produced by either epitaxial growth of single-crystal silicon on an insulating layer or by the so-called SIMOX process (Separation by IMplanted OXygen), in which high doses of high-energy oxygen ions were implanted into silicon, followed by annealing at a temperature close to the melting point of silicon, resulting in the formation of a buried layer of silicon dioxide below the thin top layer of silicon [5]. The SIMOX technique produces a high density of implantation-induced dislocations in the silicon layer. Both epitaxial growth and SIMOX processes are expensive and of low throughput. Direct silicon wafer bonding has completely changed the way SOI substrates are manufactured.

Another important application of wafer bonding is in microelectromechanical systems or MEMS. Semiconductor wafer bonding is an ideal technique to combine different structures to form functionalised elements in a three-dimensional arrangement. The first application of wafer bonding to build micro-pressure sensors was reported in 1988. Now wafer bonding has been employed in research and production of nearly all types of MEMS, including mechanical, fluidic, power, optical, medical and biological microsystems. Wafer bonding enables combination of silicon with a large variety of dissimilar materials, such as III–V and II–VI compound semiconductors, to build optoelectronic devices. It also enables transfer of MEMS devices onto a fully processed CMOS wafer to realise integration of MEMS with CMOS electronic circuits.

It must be pointed out that direct bonding of silicon wafers is not the only type of wafer bonding, though it represents the largest application of wafer bonding techniques. There are other bonding techniques, apart from *anodic bonding*, that can be considered as wafer bonding, such as eutectic bonding, adhesive bonding and glass frit bonding.

- Eutectic bonding is used when a hermetic or vacuum seal is required, generally for sensors. It uses an intermediate bonding material that forms a eutectic alloy at a specific temperature, such as gold–silicon, gold–tin or lead–silicon. The metal is usually deposited by plating, while the silicon source can be the wafer or chemical vapour deposited. Solid–liquid mixing occurs at temperatures slightly above the eutectic point and high contact force (40 kN) is produced. A hermetic solid seal forms upon cooling.
- Adhesive bonding uses photoresist, spin-on glasses or polymers to deposit a planarising material between two wafers. Such materials can be annealed or UV cured at low temperature to provide a low-stress wafer stack.
- Glass frit bonding uses glass beads (glass frit) suspended in a carrier paste and deposited onto a substrate either in a blanket form or patterned using screen printing. After deposition, the solvents are removed by degassing then heat and pressure are applied to make a hermetic seal.

Although silicon direct bonding has wide applications in MEMS and IC industries, it is not as much used in constructing micro- or nanofluidic systems because of the conductive nature of silicon wafers. Many microfluidic applications require application of an electrical field, such as those utilising *electrophoresis* and *electroosmosis*. For these applications, glass materials are preferred. A glass material permits the use of high voltages, which provides the basis for fast and efficient separation of analytes. Its

transparency allows sensitive and invasive optical detection of samples. Microfluidic applications also tend not to use adhesive or intermediate layers in wafer bonding, because they may clog the microchannels or adversely affect the liquid flow patterns.

Basic Methodology

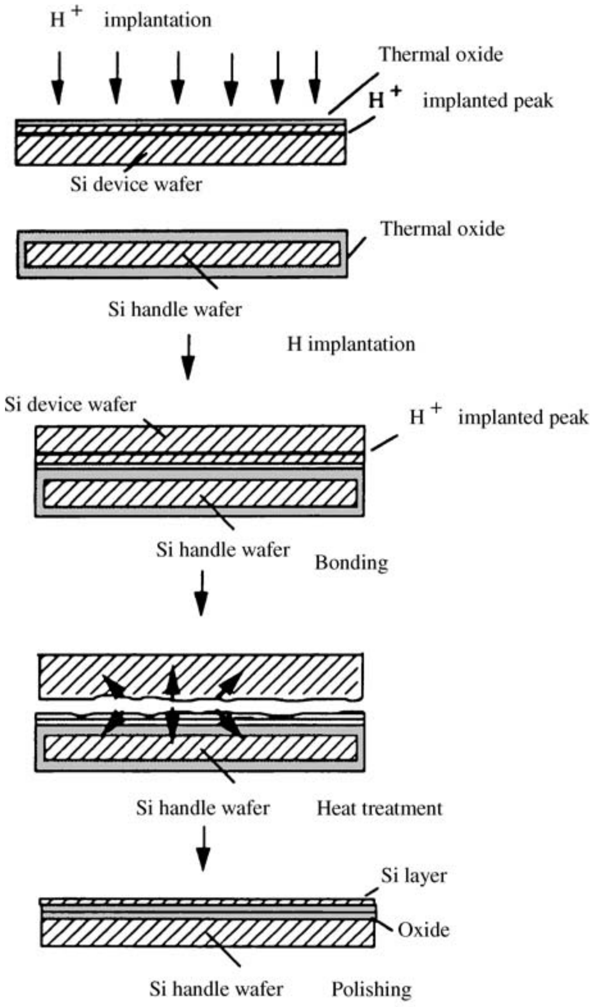
The success of direct wafer bonding is critically dependent on surface properties and conditions, chemical cleaning process and ambient conditions when the initial room temperature bonding is performed. Particles on the bonding surface will adversely affect the bonding. For example, a particle of 1 μm diameter can generate a void with a diameter of 0.5 mm which is 500 times larger the particle itself. Interfacial bubbles are often generated during the heat treatment step, which is not related to particles. Direct wafer bonding used to be a difficult manufacturing technology and sometimes characterised as *black magic* in the past [1]. Now with better understanding of the fundamental physics and chemistry of the bonding process, the technology has matured and been implemented in high-volume production. The direct wafer bonding involves four basic steps:

1. Preparation of bonding surfaces. The surfaces have to be polished mirror-like, with surface roughness less than 1 nm and thickness variation across a 4-inch wafer less than 2 μm. Normal silicon wafers straight out of the box without any processed structures are of the surface quality for direct bonding. However, if the wafer has been processed a thorough clean is necessary to remove any particulate, organic and metallic contaminations. In the meantime, the cleaning process should not degrade the surface smoothness. Hydrogen peroxide-based RCA wet solutions are commonly used for cleaning, which is also the standard cleaning solution in semiconductor manufacturing. There are two steps in cleaning: the first step is to remove any particles and organics using RCA1 ($NH_4OH : H_2O_2 : H_2O = 1 : 1 : 5$) and the second step is to remove any alkali and heavy metal contaminations using RAC2 ($HCl : H_2O_2 : H_2O = 1 : 1 : 6$) [1]. In addition to cleaning, activating the surface is highly desirable. The surface activation is to create a reactive bonding surface, for example to create the abovementioned hydrogen *bridge* bonds, so that the requirement on surface smoothness can be fairly relaxed. Activation makes the surface either hydrophobic or hydrophilic.
2. Room temperature bonding. After cleaning and activation, the two wafer surfaces are brought into contact in air and at room temperature. With a slight press to push out the thin cushion of air between the wafers, bonding occurs at the pressing area and spreads out rapidly over the entire surface within a few seconds. It must be emphasised that this step should be performed in an environment as clean as possible. Even in a *class 1* cleanroom (one 0.5 μm or larger particle in a cubic foot of air), 100% bonding yield cannot be guaranteed because of the risk of particles falling onto the bonding surface. In order to alleviate the stringent requirement on the cleanroom, special apparatus acting as a micro-cleanroom has been developed to reduce the chance of a particle dropping onto the bonding surface [1].
3. Heat treatment. This step is to convert the van der Waals weak bonds to covalent strong bonds at temperatures from 800 up to 1200 °C. Although the initial change of surface energy is different at low temperature for hydrophobic and hydrophilic surfaces, they all form the covalent bonds in the final stage of heat treatment, as shown in Fig. 1. The time of heat treatment depends on the temperature, ranging from hours to days. High temperature requires less time.
4. Wafer thinning. Although this is not a necessary step, many applications require one of the bonded wafers to be thin, from 100 nm to a few micrometres thick. This is an important step for manufacturing SOI wafers, in which the thin single-crystal silicon layer is called the device layer and the supporting silicon wafer called the handle layer. A number of techniques have been developed for wafer thinning, but the most elegant one is the *smart-cut* process [6]. As shown schematically in Fig. 2, it is based on hydrogen implantation prior to bonding. High-energy hydrogen ions implanted deep into the silicon form a buried layer which leads to cracking and splitting from the silicon wafer during heating to about 500 °C. Therefore, after implantation and bonding the top wafer can be separated from the handle wafer by heating, leaving the thin layer of silicon bonded with the handle wafer. Only a slight polishing to the splitting surface is needed to achieve the equivalent surface of a typical silicon wafer. In this way, the split-off wafer can be used again and again, because each bonding-splitting only loses a fraction of the thickness in the wafer. The smart-cut process has now become a mass production technology for manufacturing SOI wafers.

The bonding strength or surface energy after bonding can be measured by a so-called crack-opening method which is shown schematically in Fig. 3. For bonding of identical wafers ($t_{w1} = t_{w2} = t_w$, $E_1 = E_2 = E$), the surface energy per unit area γ can be expressed as [7]

$$\gamma = \frac{3Et_w^3 t_b^2}{32L^4} \tag{3}$$

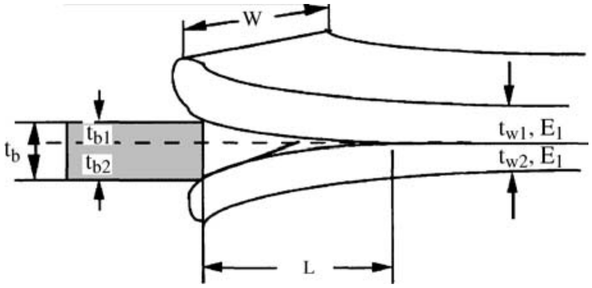
W



Wafer Bonding, Figure 2 Schematic of the *smart-cut* process for manufacturing SOI wafers

where E is the Young's modulus, t_w is the wafer thickness and L is the crack opening length. The surface energy for room temperature bonding is typically around $100\ mJ/m^2$ for hydrophilic surfaces and around $20\ mJ/m^2$ for hydrophobic surfaces. It becomes one or two orders of magnitude higher after heat treatment, as indicated in Fig. 1. For good-quality bonding, the bonding strength is that of a normal crystalline structure. Bonding uniformity or defects at bonding interface can be inspected by either infrared imaging or scanning acoustic microscopy.

Bonding of glass is also called fusion bonding. The method is more or less the same as silicon wafer bonding [8]. It requires polished surfaces, cleaning in RCA1 and RCA2 solutions. The cleaned and polished surfaces are brought into contact and heated at the temperature nearly to the melting point of glass for 6 to 8 h. For soda-lime microscope glass slides, the thermal fusion temperature is around 630 °C. For quartz substrates, the temperature can be up to 1000 °C. In most cases, a pressure applied to the bonding pair during the thermal fusion process can help to achieve a good bonding. The bonding strength is about 20 – 30 MPa, close to the strength of bulk material [9].



Wafer Bonding, Figure 3 Schematic of the crack-opening method for measuring bonding strength

Key Research Findings

The key development in wafer bonding in recent years is the low-temperature bonding technique. As mentioned above, the typical annealing temperature in silicon wafer bonding is above 800 °C. However, an increasing number of applications require temperature below 500 °C because integration of MEMS devices with a CMOS wafer has a thermal budget below 450 °C. The key to realising low-temperature wafer bonding is to modify the wafer surface: either to increase the number of hydrogen bonds or to generate new types of chemical bonds. Although some techniques utilising various intermediate layers have been developed to facilitate low-temperature bonding, the most simple and effective method is by surface activation using a plasma process. It has been found that a short plasma treatment of a bonding surface (~ 30 s) can lower the bonding temperature to 200 – 500 °C. The exact mechanism of plasma activation is not yet fully understood. For oxygen plasma, it may be due to an increase of oxide layer, combined with a higher porosity of the amorphous layer because of ion bombardment, resulting in an increasing incorporation of additional water molecules [10]. However, wafer surfaces treated in argon and nitrogen plasmas can also undergo low-temperature bonding. Recent studies indicated that the activation effect of semiconductor surfaces is mainly caused by electrons and UV radiation instead of ions. The effect of UV radiation is an additional cleaning of the surfaces by cracking of CH compounds and electrons help to generate surface-active sites, causing bonding of more OH groups [10]. Plasma activation

can also help to lower the temperature for bonding of dissimilar materials.

Future Directions for Research

Wafer direct bonding has become a key technology in semiconductor manufacturing. It offers the freedom in the design of material combination whether they are amorphous, polycrystalline, of different crystalline orientation or lattice constant. The most successful example is mass manufacturing of SOI wafers, which already has had a profound impact in the integrated circuits industry. Applications of wafer bonding in MEMS and microsystems are increasing and the technique is promised to be the key for three-dimensional integration of device structures and full integration with CMOS-based wafers. Such integration will have a significant impact on micro- and nanofluidics development. While it is a constant pursuing goal to further broaden the application of the wafer bonding technique, some basic studies are needed to better understand the mechanism of plasma activation for low-temperature bonding. Further researches are also needed to understand the physical and chemical processes of wafer bonding for materials other than silicon.

Wall Shear Stress

Synonyms

Shear stress

Definition

Wall shear stress is the tangential drag force produced by horizontal movement of the fluid across the surface. It is a function of the velocity gradient of the fluid near the surface. Its magnitude is directly proportional to fluid flow and viscosity and inversely proportional to the cube of the radius.

Direct Methanol Fuel Cell

Definition

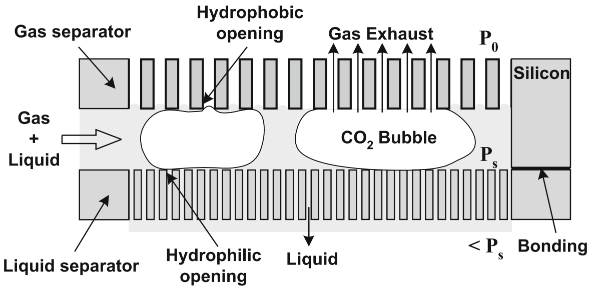
A DMFC (Direct Methanol Fuel Cell) converts the chemical energy stored in liquid methanol to usable electrical energy by a direct electrochemical oxidation-reduction reaction.

Overview

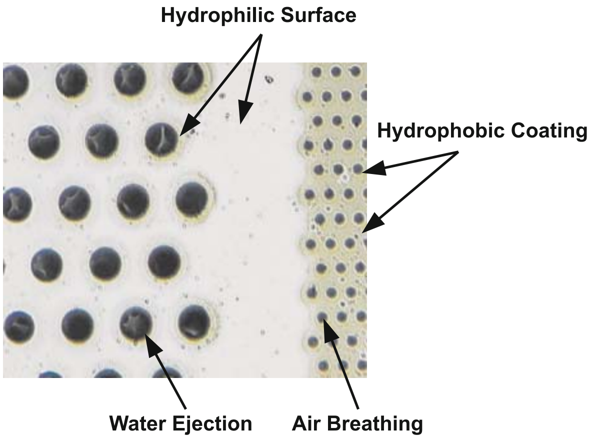
In a DMFC, methanol is directly oxidized on the surface of catalytic electrodes at the anode.

$$CH_3OH_{(l)} + H_2O_{(l)} \rightarrow CO_{2(g)} + 6H^+ + 6e^- \qquad (1)$$

The electrons are drawn to an external circuit through conductive backing layers to generate electricity, and the pro-



Water Management in Micro DMFCs, Figure 1 Schematic of a passive micro-scale CO_2 degassing system in a DMFC



Water Management in Micro DMFCs, Figure 2 Water management at the cathode of a DMFC

tons migrate through a humidified solid electrolyte (Proton Exchange Membrane, PEM) and react with oxygen at the cathode.

$$\tfrac{3}{2}O_{2(g)} + 6H^+ + 6e^- \rightarrow 3H_2O_{(l)} \tag{2}$$

Carbon dioxide (CO_2) evolves on the anode surface in the form of gas bubbles, impeding methanol supply to the catalyst surface. Surface treatment with a selective hydrophobic coating on the backing layer is used to assist CO_2 bubble scrubbing [1]. CO_2 bubbles escaping from the catalyst surface accumulate in the internal fuel circulation loop. The resulting two-phase flow drastically increases the flow resistance of the fuel circulation loop and may totally choke the flow path. A passive CO_2 degassing system, consisting of two parallel plates with an array of etched-through holes, is shown in Fig. 1 [2]. The wettability of the surface of the gas separator is modified by a thin layer of hydrophobic coating to facilitate gas bubble removal from the gas-liquid mixture. The coating also prevents fuel leakage through the openings by forming a meniscus at the mouth of the openings inside the system. The maximum sustainable opening diameter (D_{max}) to avoid liquid leakage can be approximated by the well-known Young–Laplace equation.

$$D_{max} = \frac{4\gamma\cos(180^\circ - \theta)}{P_s - P_0} \tag{3}$$

where γ is the surface tension of the fuel mixture, θ is the contact angle (in degree) of the fuel mixture on the hydrophobic surface, P_s is the system pressure and P_0 is the ambient pressure. The liquid separator, on the other hand, is hydrophilic in order to create an effective passage for the liquid flow.

Water is generated at the cathode. The excessive water may result in flooding, reducing the effective surface area of the cathode available for the reduction reaction and hence, lowering the entire electrochemical reaction rate. The same concept of preferential surface wettability modification used in the passive CO_2 degassing system can be applied to resolve this water management issue. As shown in Fig. 2, a hydrophobic thin film is coated on the area with small openings to allow air (oxygen) "breathing", while the surface of the area with large openings remains hydrophilic to assist water removal from the cathode surface [2]. The water expelled from the cathode through the openings is guided and collected along the hydrophilic surface without cross-covering the area with small. Part of the collected water can then be recycled back to the anode to maintain the electrochemical reaction.

Weak Formulation

Synonyms

Generalized formulation

Definition

A weak formulation is an equation derived from the original (strong) formulation of a physical problem by alleviating the strict differentiability requirements for the unknown function. This is often achieved by lowering the order of partial derivates appearing in the equation for instance using integration-by-parts.
The solution to a weak formulation associated to an ordinary or partial differential equation is called the weak (or generalized) solution. There are many different definitions of weak solution, appropriate for different classes of equations.
Weak solutions are important in engineering because a large number of differential equations which are used to describe real world phenomena do not admit smooth enough solutions. Weak formulations provide a way to solve such problems.

Weber Number

Definition

The dimensionless *Weber number* represents the ratio of disruptive hydrodynamic forces to the stabilizing surface tension force. Hence, the *Weber number* indicates whether the kinetic or the surface tension energy is dominant. For a spherical droplet the *Weber number* can be derived using the kinetic energy compared to the surface energy.
The *Weber number* can be used for two different declarations. On the one hand it describes whether a droplet can leave a nozzle at all due to higher kinetic energy compared to surface energy. On the other hand it can describe whether a droplet has the tendency for splashing when the kinetic energy is released at the impact on a surface.
The higher the *Weber number* the more dominant is the kinetic energy. This means that most of the inserted energy converts into kinetic energy, i. e. an ejected droplet is faster with higher *Weber number*. The lower the *Weber number* the more dominant is the surface tension energy. This means that most of the inserted energy converts into surface tension energy, i. e. a droplet formation is critical or even impossible.
The *Weber number* is the most important dimensionless number characterizing the droplet formation. Therefore, the *Weber number* can be used to distinguish between occurring droplet formation regimes.

Wet Etching

Definition

Wet etching is a fabrication process of using liquid chemicals or wet etchants (a mixture of acids, base, water and other chemicals) to dissolve the bulk substrate or thin film such as silicon,GaAs,SiC,SiO_2,Si_3N_4 and metals. In

W

microfabrication applications, it is widely used to transfer the designed patterns from an etching mask to the substrate. When the sample is immersed into the etching bath, the etchant only contacts and reacts with the substrate surfaces where are uncovered by the etching mask. The suitable materials for the mask can be polymers or other materials such as photoresist, SU-8,SiO_2 andSi_3N_4, which feature much lower etching rate in the selected etchant in contrast to the substrate material.

Wet etchants fall into two broad categories: isotropic etchants and anisotropic etchants. Isotropic etchants attack the material being etched at the same rate in all directions. Anisotropic etchants attack some single-crystal materials (typically silicon) at different etch rates depending on the crystallographic orientation of the substrate, so there is more control of the shapes being produced.

Wet etching is the most common processing in semiconductor industry and MEMS applications.

Capillarity

Definition

The wettability of a liquid governs how it spreads over a solid substrate or an immiscible liquid phase and is characterized by a contact angle, which is the angle subtended by the liquid/vapor interface and the solid or immiscible liquid surface. Depending on the surface energy of the substrate, two equilibrium situations can occur upon contact of the liquid and the solid. *Complete wetting* corresponds to the situation when the surface energy of the substrate is high and hence the liquid spreads entirely over (or wets) the solid, thereby forming a film in which case the contact angle is zero. *Partial wetting*, on the other hand, relates to the situation when the surface energy of the substrate is low and hence a finite contact angle is obtained in which case the liquid retains its drop shape which is restricted at the solid surface by a contact line where the solid, liquid and vapor phases meet. The governing principle is the minimization of interfacial energy; in the former case, the interfacial contact between the liquid film and the solid substrate minimizes the free energy of the surface.

Overview

Wetting and spreading, the subject of which is a fundamental pillar of colloid and interface science, are fundamental processes which occur in a wide variety of natural and industrial settings. These processes govern the adhesion between two substances and therefore have significant implications in paint, lubrication, coating, printing and fabric technology as well as in enhanced oil recovery. More recently, there has been renewed interest in the relevance of wetting and spreading in biological and microscale environments. The functional design of biomaterials and biological surfaces requires a thorough understanding of the interrelationships of bio-surfaces and bio-environments. The miniaturization of fluid processes, on the other hand, is associated with an increase in the dominance of surface forces over body forces given that the surface area to volume ratio scales as the inverse of the characteristic system dimension. Thus, at microscale dimensions, surface tension and hence wettability (or capillarity) effects are extremely important considerations in the design of microfluidic devices.

Basic Methodology

Surface Tension and Contact Angle

The relationship between surface tension γ and contact angle θ, formally defined as

$$\theta = \cos^{-1}(\boldsymbol{n}_l \boldsymbol{n}_s) , \tag{1}$$

where $\boldsymbol{n}_l$ and $\boldsymbol{n}_s$ are the outward pointing unit normal vectors from the liquid and solid at the three-phase contact line, respectively, was first established by Thomas Young

in 1805 through a force balance in the plane of the surface at the contact line (Fig. 1):

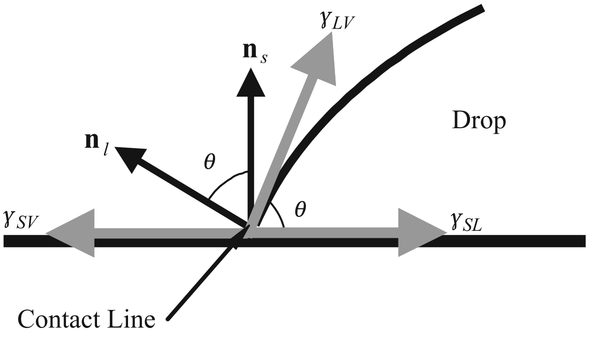
$$\gamma_{\mathrm{LV}} \cos\theta = \gamma_{\mathrm{SV}} - \gamma_{\mathrm{SL}} , \tag{2}$$

where the subscripts LV, SV and SL denote the liquid-vapor, solid-vapor and solid-liquid phases, respectively. Equation (2) is thus known as *Young's equation*. It should be noted that a force balance also exists in the plane normal to the surface due to the existence of a strain field beneath the contact line to balance the force component $\gamma_{\mathrm{LV}} \sin\theta$. In the case of a liquid lens sitting at the interface of an immiscible liquid, the lens shape is governed by this force balance, the resultant of which is zero (Fig. 2). Equation (2) can also be derived by energy minimization considerations.

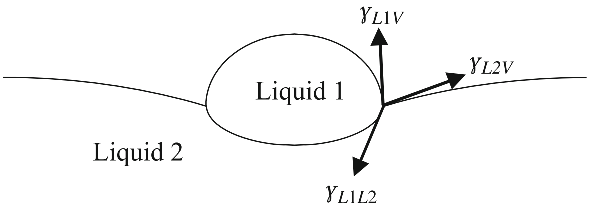
The spreading of the drop can be characterized by a spreading coefficient:

$$S = \gamma_{\mathrm{SV}} - \gamma_{\mathrm{SL}} - \gamma_{\mathrm{LV}} . \tag{3}$$

If $S \geqslant 0$, complete spreading occurs in which the drop spontaneously forms a liquid film above the solid substrate, as shown in Fig. 3(a), due to a decrease in the free energy. If $S < 0$, $\theta > 0°$ from Eq. (2) and the drop spreads to an equilibrium shape, constrained by the contact line where the three phases meet; if $\theta < 90°$, the surface is said to be *hydrophilic* (Fig. 3(b)) whereas the surface is said to be *hydrophobic* if $\theta > 90°$ (Fig. 3(c)). Strictly speaking, there is no local minimum in the interfacial energy for $S > 0$ and hence the equilibrium contact angle $\cos\theta$ cannot be defined by Eq. (2). The minimum is defined at $S = 0$, which from Eqs. (2) and (3) gives $\cos\theta = 1$ or $\theta = 0°$, corresponding to the complete wetting case.



Wetting and Spreading, Figure 1 Force balance at the three-phase contact line where the solid-liquid and vapor phases meet. The outward unit normals protruding from the solid and liquid at the contact line are shown. The angle θ subtending these unit normal vectors or that subtending the interface between the drop and the solid substrate is known as the contact angle



Wetting and Spreading, Figure 2 Force balance at the contact line of a liquid lens sitting above an immiscible liquid

The contact angle is known as a *static* contact angle when the contact line is stationary with respect to the solid substrate. Young's equation in Eq. (2) is therefore a description of the static contact angle. On the other hand, if the contact line is moving relative to the solid, the contact angle, whether it is advancing or receding, is known as a *dynamic* contact angle. The dynamic contact angle varies with the speed at which the contact line advances (or recedes). The upper theoretical limit of the receding contact line speed is therefore the case of complete wetting where the dynamic contact angle approaches 0°. The opposite completely non-wetting limit can be seen when the bulk of the advancing fluid and hence the drop interface overtakes the contact line and hence entrains the fluid being displaced. An example of this is in gravity driven fronts in which the advancing front of the drop forms a nose which rolls over the contact line, as shown in Fig. 4, in which case the dynamic contact angle would approach 180°; in this case, the entrained fluid is therefore the air surrounding the drop. In the extreme completely non-wetting case $\theta = 180°$, a thin submicroscopic film of the displaced phase is entrained beneath the drop therefore causing the complete disappearance of the contact line.

A point should be made here about superhydrophobic surfaces, over which a drop can translate via two states. In a suspended state, the drop sits atop the apex tips of the rough surface; air is entrained beneath the drop and fills the interstices of the rough surfaces between the apex tips. In this state, it has been shown that the velocity of the drop increases with increasing contact angles. Although this may seem contradictory to the classical view above, it is this author's view that the contact line receding speed remains low but the drop itself slides over the entrained air layer due to bulk convection. The increasing bulk drop velocity with increasing contact angles is attributed to the higher center of mass of the drop [1]. For drops in a collapsed state, wherein the liquid fills the interstices of the rough surface, the drop velocity is reduced dramatically each time the contact line reaches a cavity and a stick-slip motion is therefore observed.

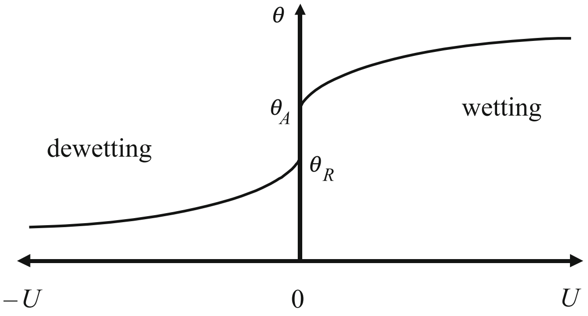
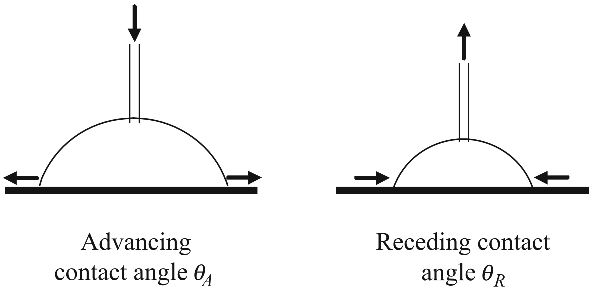
Wetting and Spreading, Figure 4 Schematic depiction of contact angle hysteresis arising when the solid substrate upon which a drop is placed is inclined. At the instance prior to the drop moving down the plane, the contact angle at the advancing front and at the rear are known as the advancing and receding contact angles, respectively



Wetting and Spreading, Figure 5 Contact angle hysteresis arising due to the dependence of the apparent contact angle θ on the contact line velocity *U*

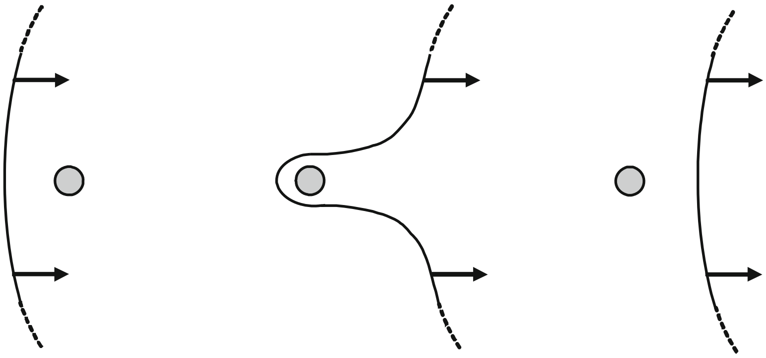


Wetting and Spreading, Figure 6 Measurement of the advancing and receding contact angles by incrementally adding or removing liquid through a thin capillary tube. The measurements are taken just prior to motion of the contact line

The boundary between the static and dynamic conditions also gives rise to contact angle hysteresis, in which the static contact angle when the contact line velocity U is zero is not single-valued (as predicted by Eq. (2)), as shown in Fig. 5, which maps out the velocity dependence of the contact angle. The static contact angle at equilibrium θ appears to be dependent on the history of the drop, i. e., on whether it is on the verge of advancing or receding. The observed contact angle at the front just before the inclined drop in Fig. 4 begins to slide is known as the *advancing* contact angle θ_A whereas that at the rear is known as the *receding* contact angle θ_R. Alternatively, the advancing and receding contact angles can be obtained by measuring the contact angle of a sessile drop just prior to motion when liquid is added or removed from a capillary above the drop to drive it to advance or recede, respectively, as illustrated in Fig. 6. The difference in the advancing and receding angles, i. e., $\theta_A - \theta_R$ (typically 10° or larger), is therefore the contact angle hysteresis, and the equilibrium static contact angle takes any intermediate value in between these limits, i. e., $\theta_R \leqslant \theta \leqslant \theta_A$.

Contact angle hysteresis can be attributed to a departure from the conditions of ideality of the solid, namely, surface roughness, chemical inhomogeneities or contamination, or, the presence of solute (polymers or surfactants) deposits on the surface [2]. Figure 7 shows a plan view illustration of the hysteresis mechanism in which the receding contact line of a drop is locally pinned when the drop moves over a localized surface inheterogeneity which is more hydrophilic than the substrate surface. As a result, there is a distortion of the contact line [3]. If the macroscopic force exerted on the contact line is

$$F = \gamma_{LV} \left(\cos\theta' - \cos\theta\right) , \quad (4)$$

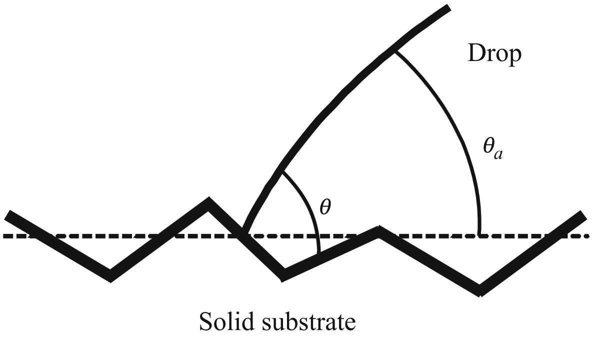


Wetting and Spreading, Figure 7 Plan view illustrating the pinning of the receding contact line due to the presence of a localized surface heterogeneity (represented by the shaded spot) which is more hydrophilic than the substrate. The arrows indicate the direction of the drop motion

where θ' is the contact angle of the drop and θ is the equilibrium contact angle given by Young's equation (Eq. (2)), we note that it is not possible to detach the contact line below a given value of the force and hence the contact line remains pinned for contact angles θ' below that of the equilibrium contact angle θ. In such cases and when evaporation is significant, there arises liquid flow from the bulk of the macroscopic drop in order to replenish the liquid evaporated from the contact line region. If solutes are present in the liquid, these are convected towards the contact line and deposited there, resulting in the formation of concentrated rings along the perimeter of the contact line; an example of this is the ubiquitous coffee-ring stain phenomenon.

A distinction between the *apparent* (or visible) contact angle θ_a and the intrinsic contact angle θ is worthy of mention. The apparent contact angle is a macroscopic extrapolation whereas the intrinsic contact angle is that microscopically subtended from the solid substrate at the contact line, as schematically depicted for a rough surface in Fig. 8. The advancing and receding contact angles due to contact angle hysteresis therefore relate to apparent contact angles. Thus, were the surface ideal, i. e., atomically smooth, clean and homogeneous such that Eq. (2) holds, then the apparent contact angle should coincide with the intrinsic contact angle to describe the equilibrium static contact angle.

Nevertheless, for most practical surfaces, this is not true and hence the intrinsic contact angle is difficult to determine. The surface heterogeneities could very well be the reason why the wetting line moves in a hesitant jerk or shuffling motion, termed as *stick-slip* motion [4]. This could also be attributed to the successive formation and collapse (due to negative disjoining pressure) of the entrained air film beneath the drop. Changes to the apparent contact angle, nevertheless, can be evaluated for rough



Wetting and Spreading, Figure 8 Schematic depiction of the contact line region on a microscopic level illustrating the distinction between the apparent (macroscopic) contact angle θ_a and the intrinsic (microscopic) contact angle θ due to surface roughness effects on the substrate

surfaces. Consider a small displacement of the contact line dx on a rough but chemically homogeneous surface, as shown in Fig. 9(a). The change in the surface energy per unit length along the contact line dE is then

$$dE = (\gamma_{SL} - \gamma_{SV})\, r dx + \gamma_{LV} \cos\theta^* dx\,, \quad (5)$$

in which r is the surface roughness (assumed to be much smaller than the macroscopic drop length scale) and θ^* denotes the contact angle on the rough surface ($r > 1$).

At equilibrium, the resultant surface forces at the contact line balance and hence the energy is at its minimum, i. e., $dE/dx = 0$. Wenzel's law, derived from this equilibrium condition $dE/dx = 0$ together with Eq. (2) (which can be recovered from Eq. (5) for smooth surfaces where, by definition, $r = 1$), then states

$$\cos\theta^* = r\cos\theta\,, \quad (6)$$

W

wherein θ is the contact angle for smooth surfaces given by Young's equation (Eq. (2)). Since $r > 1$ for rough surfaces, $|\cos\theta^*| > |\cos\theta|$, implying that surface heterogeneities always act to amplify the inherent properties of a surface. In other words, a hydrophilic surface ($\theta < 90°$) will be rendered more hydrophilic ($\theta^* < \theta$) and a hydrophobic surface ($\theta > 90°$) will be rendered more hydrophobic ($\theta^* > \theta$) in the presence of surface roughness.

A similar analysis can be carried out for physically smooth but chemically inhomogeneous surfaces, as depicted in Fig. 9(b), where we allow the surface to comprise of two different materials, each of which is associated with a corresponding contact angle, θ_1 and θ_2. Denoting the fractions along the surface which is composed by each material as f_1 and f_2 (such that $f_1 + f_2 = 1$), assuming f_1 and f_2 are small compared to the area occupied by the entire drop, Eq. (5) now becomes

$$\mathrm{d}E = f_1(\gamma_{SL} - \gamma_{SV})_1\,\mathrm{d}x + f_2(\gamma_{SL} - \gamma_{SV})\,2\mathrm{d}x + \gamma_{LV}\cos\theta^*\mathrm{d}x\,. \tag{7}$$

Energy minimization then requires

$$\cos\theta^* = f_1\cos\theta_1 + f_2\cos\theta_2\,, \tag{8}$$

which is known as the Cassie–Baxter law. In this case, the apparent contact angle due to the chemical inhomogeneous surface is the average of the cosines of the contact angles associated with each chemical that the surface is comprised of, and is hence bounded by the two extremes of these contact angles.

Capillarity

The equilibrium drop shape is related to the surface tension of the drop through its curvature. In other words, the tendency for the drop to assume a curved interfacial shape is due to its surface tension. A consequence of this is the existence of a pressure difference across the interface

$$\Delta p = \gamma_{LV}\kappa\,, \tag{9}$$

with the highest pressure residing on the concave side.

$$\kappa = \frac{1}{R_1} + \frac{1}{R_2}\,, \tag{10}$$

is twice the mean curvature wherein R_1 and R_2 are known as the principal radii of curvature, which is the radii of curvature of the interface along any two orthogonal elements. Equation (9) is known as the *Laplace–Young equation*. For a spherical drop or bubble, $R_1 = R_2 = R$ and hence

$$\Delta p = p_i - p_e = \frac{2\gamma_{LV}}{R}\,, \tag{11}$$

where p_i and p_e are the pressures inside and outside the drop or bubble, respectively.

Capillarity is the phenomena that arises due to the existence of a finite (or even zero) contact angle that a liquid makes with the solid substrate. One example is the height-of-rise of a liquid in an open capillary tube, as shown in Fig. 10. The associated liquid motion due to surface tension is known as *capillary flow*. Assuming the meniscus to be approximately hemispherical with constant radius of curvature $R_1 = R_2 = R/\cos\theta$, where $2R$ is the capillary diameter, the pressure variation across the interface from Eq. (11) is then

$$\Delta p = p_{atm} - p_{liq} = \frac{2\gamma_{LV}\cos\theta}{R}\,, \tag{12}$$

where p_{atm} and p_{liq} are the atmospheric and liquid pressures, respectively. Given that at equilibrium, the hydrostatic head of the liquid capillary $p_{liq} + \rho g H$, where ρ is the liquid density, g the gravitational acceleration and H the equilibrium height of the liquid capillary column, must balance the atmospheric pressure, i. e.,

$$p_{liq} + \rho g H = p_{atm}\,, \tag{13}$$

H can then be obtained by substituting Eq. (12):

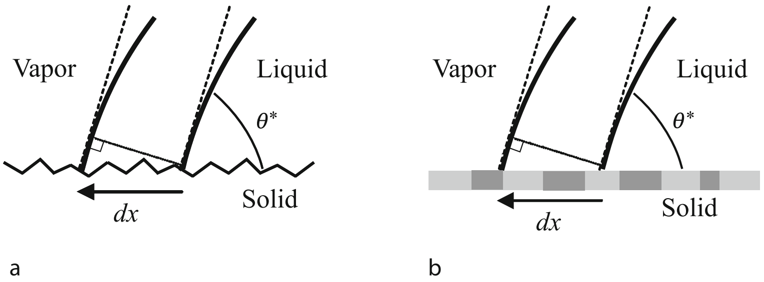
$$H = \frac{2\gamma_{LV}\cos\theta}{\rho g R}\,. \tag{14}$$

Equation (14) therefore represents an equilibrium dominant balance between the gravitational and surface tension forces. Thus, given that ρ and $\cos\theta$ are known for a given fluid, the capillary rise can be determined. It is also evident from Eq. (14) that the capillary rise is dependent on the capillary radius. For small capillaries, H can therefore become relatively large. This capillary rise method is therefore very useful and accurate for measuring the surface tension of liquids.

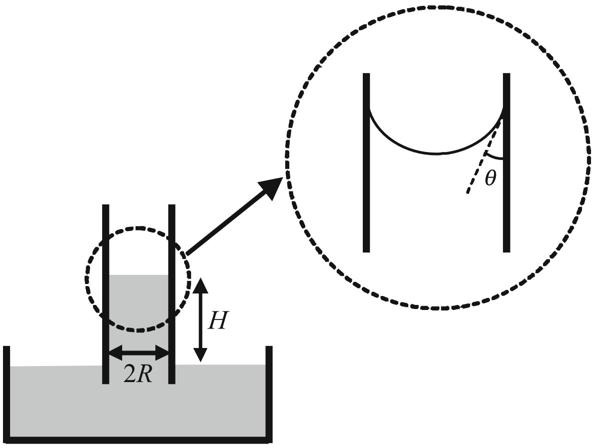
Key Research Findings

Spreading Dynamics

We briefly consider the spreading dynamics of a drop, sufficiently small such that the spreading is not influenced by gravity. We will also assume the substrate to be smooth and homogeneous since surface roughness effects can enhance spreading and even lead to the spontaneous wetting of partially wetting liquids. The interface is also assumed to be



Wetting and Spreading, Figure 9 Contact line region of a drop on a (**a**) physically rough but chemically homogeneous surface, and, (**b**) a physically smooth but chemically inhomogeneous surface consisting of two different surface materials. A small displacement to the contact line $\mathrm{d}x$ is considered in the derivation of Wenzel's law in the case of (**a**) and the Cassie–Baxter law in the case of (**b**)



Wetting and Spreading, Figure 10 Schematic depiction of a capillary height-of-rise experiment

clean such that no surface tension gradients are imposed, which could lead to Marangoni stresses; such effects will be discussed subsequently. The experimentally observed spreading data for complete wetting then appears to follow a simple power law relationship given by

$$R(t) \sim t^n \,, \tag{15}$$

where R is the radius of the spreading drop and t denotes time. n has been empirically found to lie between 0.1 and 0.14; it's value has been reported to be dependent on the drop volume, temperature and physical properties as well as the humidity of the ambient phase.

There is also a very specific scaling for the macroscopic dynamic contact angle θ. This was first observed by Hoffman [5], who investigated the variation in the contact angle of an advancing meniscus front in a capillary tube subject to different fluid driving velocities, as well as Tanner [6], who observed similar behavior for drops spreading on a horizontal substrate. In both cases, it was observed that for small Ca,

$$\theta \sim \mathrm{Ca}^{\frac{1}{3}} \,, \tag{16}$$

where

$$\mathrm{Ca} \equiv \frac{\mu U}{\gamma} \,, \tag{17}$$

is the capillary number with $U(t) = \mathrm{d}R(t)/\mathrm{d}t$ being the speed of the contact line in the above, μ is the viscosity. The universal law given by Eq. (16) has since been corroborated by many investigators.

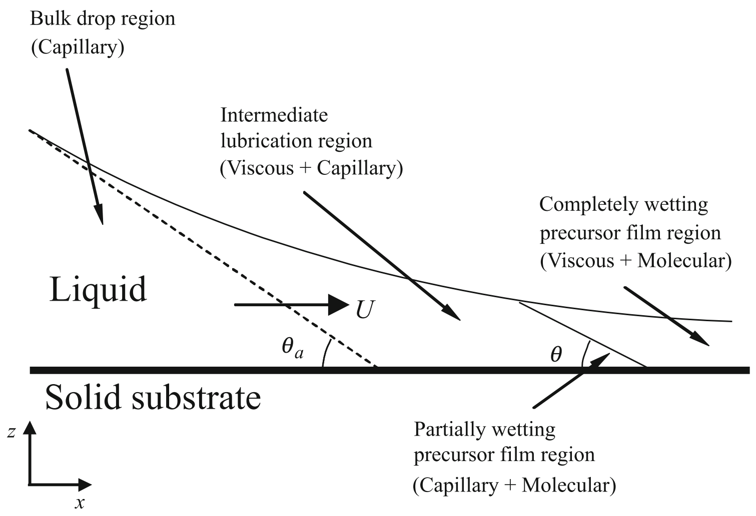
Kalliadasis and Chang [7] considered the behavior of the asymptotic region between the bulk macroscopic drop and a thin film ahead of the drop in which liquid from the perfectly wetting drop drains into due to the negative disjoining and capillary pressures, as shown in Fig. 11. This thin film, known as the precursor film, has both been observed experimentally [8] and is also used as a convenient means of removing mathematical difficulties near the contact line region where continuum theory breaks down; a discussion of this will be carried out below. In this asymptotic region between the bulk drop, of characteristic length scale L, and the precursor film region, of characteristic length scale $\hat{L}$, viscous and capillary forces dominate.

Thus, assuming the film in this region to be thin such that the lubrication approximation holds, the spreading dynamics of the drop in the limit $\hat{L}/L \ll 1$ and the local quasi-steady limit with respect to a moving coordinate frame translating at a constant dimensionless speed given by Ca, is governed by the Bretherton [9] equation:

$$3\,\mathrm{Ca}\frac{\partial h}{\partial x} = \frac{\partial}{\partial x}\left(h^3\frac{\partial^3 h}{\partial x^3}\right) , \tag{18}$$

where h is the dimensionless film height, scaled by the characteristic height of the macroscopic drop H. In the

W



Wetting and Spreading, Figure 11 Contact line region of a spreading drop ahead of which a thin front running precursor film exists. The intermediate asymptotic region where viscous and capillary forces dominate is shown. After Kalliadasis and Chang [7]

above, the axial and vertical coordinates, x and z are scaled by L and H, respectively. Kalliadasis and Chang [7] then showed that the film height, upon redimensionalization, assumes the following weak logarithmic behavior as it asymptotes away from the contact line:

$$h \sim -x\,\mathrm{Ca}^{\frac{1}{3}} \left(9 \log \frac{\hat{L}}{L}\right)^{\frac{1}{3}} . \tag{19}$$

A dynamic contact angle condition can then be written for the macroscopic spreading drop:

$$\tan\theta \sim -\frac{\partial h}{\partial x} \sim \left(-9 \log \frac{\hat{L}}{L}\right)^{\frac{1}{3}} \mathrm{Ca}^{\frac{1}{3}} , \tag{20}$$

showing that the local quasi-steady spreading of a partially or completely wetting liquid drop at constant speed Ca driven by viscous and capillary forces always gives rise to an interfacial shape that scales consistently with the universal law given in Eq. (16). Equation (20) suggests that away from the static equilibrium limit, a partially wetting drop behaves, albeit quite surprisingly, like a complete wetting drop, consistent with the experimental findings for sufficiently large Ca [7].

It is now possible to insert this dynamic contact angle condition back into the spreading relationship in Eq. (15) to obtain an explicit power law for the spreading dynamics of a drop lying on a horizontal substrate [7]. If the drop can be assumed to be thin, then the axisymmetric Laplace–Young equation in the lubrication limit reads

$$\frac{\partial}{\partial r}\left[\frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial h}{\partial r}\right)\right] = 0 . \tag{21}$$

The following boundary conditions apply

$$\frac{\partial h}{\partial r}(r=0) = 0 , \quad h(r=R) = 0 , \quad \text{and,}$$
$$\frac{\partial h}{\partial r}(r=R) = -\tan\theta . \tag{22}$$

In addition, we impose conservation of the drop volume V:

$$\int_0^R hr\,\mathrm{d}r = \frac{V}{2\pi} . \tag{23}$$

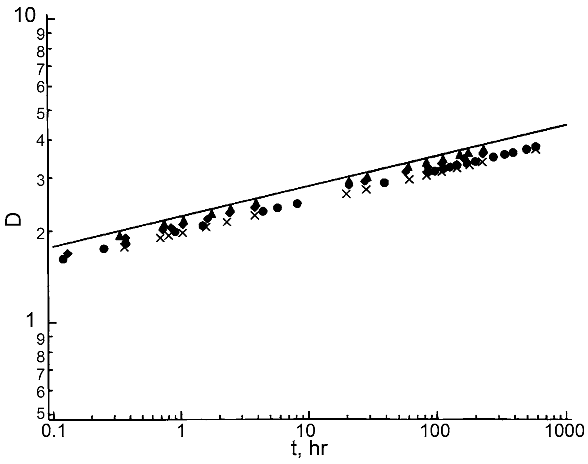
Integrating Eq. (21) twice subject to the boundary conditions above then yields

$$h(r) = \frac{2V}{\pi R^2}\left[1 - \left(\frac{r}{R}\right)^2\right] . \tag{24}$$

Substitution of the dynamic contact angle condition in Eq. (20) then gives

$$\frac{\partial h}{\partial r}(r=R) = -\frac{4V}{\pi R^3} = \left(9 \log \frac{\hat{L}}{L}\right)^{\frac{1}{3}} \mathrm{Ca}^{\frac{1}{3}} . \tag{25}$$

Since the dimensionless advancing speed of the contact line can be written as $\mathrm{d}R/\mathrm{d}t = 3\,\mathrm{Ca}$, where time is scaled



Wetting and Spreading, Figure 12 Collapse of the poly(dimethylsiloxane) drop spreading data of Ausserré et al. [8] with the dimensional form of the universal law given by integration of Eq. (26), which is denoted by *D*. Reproduced with permission from [8]

by $\mu L/\gamma$ and the radius by $V^{1/3}$, it then follows that

$$\frac{\partial R}{\partial t} = -\frac{512V}{3\log\left(\hat{L}/L\right)R^9}\,, \tag{26}$$

and hence

$$R \sim t^{\frac{1}{10}}\,, \tag{27}$$

consistent with the dynamic spreading law of Eq. (15). The collapse of the experimental data of [8] for the spreading of poly(dimethylsiloxane) drops of various volumes on a silicon substrate is shown in Fig. 12 [7]. On the other hand, for large drops where gravity would play an influence, the drop radius would spread as $R \sim t^{1/8}$ instead.

Stress Singularity

In addition to the challenges in the treatment of free surfaces, dynamic spreading models encounter a significant conceptual difficulty due to the breakdown of continuum hydrodynamics at the contact line when the sharp continuum interface is extrapolated to molecular scales to define the contact angle. At these microscopic scales, such geometric conceptualizations such as an interface and the contact angle becomes ambiguous. Moreover, the enforcement of the slip-free and tangential stress continuity on the smooth solid substrate at the three-phase contact line gives rise to a stress singularity [4]. In other words, a logarithmically infinite force is required to advance the contact line, which is not observed experimentally [10]. This locally unbounded force is not the result of a kinematic incompatibility between the no-slip condition on the substrate and the existence of an advancing drop interface that is impenetrable by both sides of the fluid [11]. Instead, Dussan and Davis [11] suggest that the stress singularity is a dynamic consequence of the multi-valued velocity field at the contact line.

Various models have been proposed to overcome this difficulty. Early models allowed the continuum theory to define the contact angle up to a molecular cut-off. One approach is to allow for a finite slip velocity such that the stress singularity, whilst not removed altogether, becomes a logarithmic singularity that is at least integrable [12, 13]. Another approach that we have discussed above is to assume that a thin precursor film precoats the substrate [14]. Alternatively, given that wetting is driven by molecular forces at the inner region of the contact line, the disjoining pressure arising from long-range intermolecular interactions can be introduced to account for a negative pressure that sucks liquid from the bulk into the precursor film.

Nevertheless, it has been shown that the same asymptotic behavior of the inner region away from the contact line given by the universal solution of Eq. (19) is recovered regardless of which model above is adopted to remove the contact line stress singularity in both partially or completely wetting fluids [15]. In fact, the dimensionless length scale $\hat{L}/L$ can be shown to be equal to the precursor film thickness b, i. e.,

$$\frac{\hat{L}}{L} \sim \frac{b}{H}\,, \tag{28}$$

if the precursor film is adopted, the Hamaker constant α, i. e.,

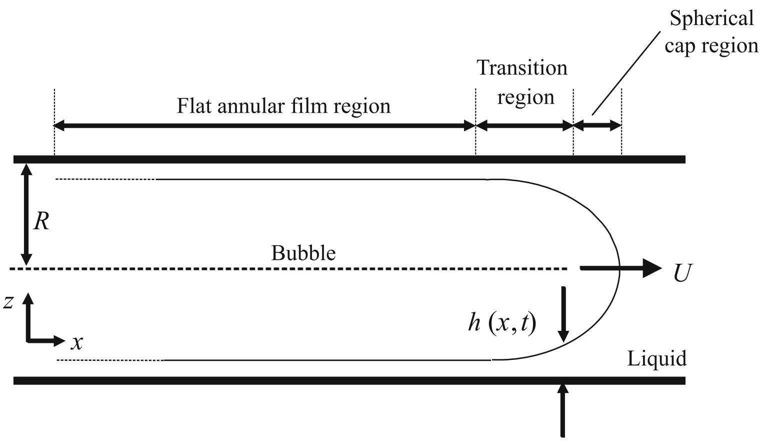
$$\frac{\hat{L}}{L} \sim \frac{1}{L}\left(\frac{|\alpha|}{6\pi\gamma}\right)^{\frac{1}{2}}\,, \tag{29}$$

if the disjoining pressure is used, and, the slip coefficient $\lambda_i = \lambda h^i$, i. e.,

$$\frac{\hat{L}}{L} \sim \lambda_i^{\frac{1}{(1+i)}}\,, \tag{30}$$

if a slip model is employed; λ is the film thickness dependent slip length, the dependence of which is given by the exponent i $(=0, 1)$ and corresponds to the different slip models historically used [16].

To leading order, the intermolecular forces are shown to be solely determined by the apparent dynamic contact angle and independent of slip. The precursor film is also shown to be reasonable approximation to account for intermolecular effects although both the precursor film and slip



Wetting and Spreading, Figure 13 Schematic depiction of a bubble translating within a long capillary tube

models, while mathematically convenient for handling the problem of stress singularity, do not appear to contribute to the dynamic contact angle condition. In any case, imposing one or the other does not lead to significant error due to the weak dependence of the coefficient $-9\log(\hat{L}/L)$ on the asymptotic behavior of the bulk drop region [15].

Capillary Driven Spreading

We have already observed an example of capillary-driven spreading in the capillary rise experiment described above. Another example of capillarity is that of bubble transport in capillary tubes [9]. Scaling arguments for this problem, illustrated in Fig. 13, are discussed by Chang [17]. To leading order, the pressure drop at the front and rear spherical caps are given by Eq. (11) and thus the axial curvature is $1/R$, where R is the radius of curvature of the bubble cap. In the short intermediate transition region of length L_0 between the spherical cap and annular film regions, the azimuthal curvature gradient, which scales as H_0/R^2L_0 given that the azimuthal curvature is $1/(R-h)$, is negligible compared to the axial curvature gradient, which scales as H_0/L_0^3 since the axial curvature is $\mathrm{d}^2h/\mathrm{d}x^2$ (that $L_0 \ll R$ will be explicitly shown below in Eq. (33)); h is the liquid film thickness with a characteristic length scale in the transition region of H_0 and x is the axial coordinate. Asymptotic matching between the transition and cap regions then gives rise to a balance between the axial and azimuthal curvatures:

$$\frac{H_0}{L_0^2} \sim \frac{1}{R} \,. \tag{31}$$

A balance between viscous and capillary forces requires

$$\frac{\mu U}{H_0^2} \sim \frac{\mathrm{d}p}{\mathrm{d}x} \sim \frac{\gamma}{RL_0} \,, \tag{32}$$

where U is the speed of the bubble. It then follows from Eqs. (31) and (32), with the dimensionless speed Ca defined by Eq. (17), that

$$H_0 \sim R\,\mathrm{Ca}^{\frac{2}{3}} \,, \text{ and} \,, \quad L_0 \sim R\,\mathrm{Ca}^{\frac{1}{3}} \,, \tag{33}$$

as long as $\mathrm{Ca} \ll 1$.
To render the problem quasi-steady, a moving coordinate frame is adopted such that the bubble translates at speed Ca. In the thin annular film region, application of the lubrication approximation to a balance between viscous and capillary forces then yields the following dimensionless equation for the film thickness h [17]:

$$h^3 \frac{\mathrm{d}^3 h}{\mathrm{d}x^3} = h - 1 \,, \tag{34}$$

where h is scaled by the characteristic height of the film H_0 and x by $H_0(3\,\mathrm{Ca})^{-1/3}$. Equation (29) describes the asymptotic behavior in the transition regions for both the front spherical cap as $x \to \infty$ and the rear spherical cap as $x \to -\infty$. Since a quadratically increasing film height is expected, we allow

$$h = A^{\pm}x^2 + B^{\pm}x + C^{\pm} \,, \tag{35}$$

where A, B and C are constants in which the + subscript denotes that pertaining to the front cap and the − subscript pertains to the rear cap. These can be obtained by numerical integration of Eq. (34) starting from the flat film where $\mathrm{d}h/\mathrm{d}x = \mathrm{d}^2h/\mathrm{d}x^2 = 0$, noting that B can be set to zero by arbitrarily shifting the origin. It is then possible to match the curvature $\mathrm{d}^2h/\mathrm{d}x^2$ of the asymptotic solution in Eq. (35) to the outer spherical cap solutions, which to

leading order, are static solutions of the Laplace–Young equation. Chang [17] showed that this leads to

$$\frac{H_0}{R} = 0.643\,(3\,\mathrm{Ca})^{\frac{2}{3}}\ , \tag{36}$$

which is an estimate of the film thickness to leading order. Similar scalings can also be observed in coating flows wherein solid substrates are coated with a thin and uniform liquid film.

Marangoni and Thermocapillary Driven Spreading

In our discussion above, we had assumed that the interface is clean and isothermal. However, surface impurities and non-uniform temperatures can alter the local surface tension, thus giving rise to surface tension gradients that generate additional interfacial stresses, the so-called Marangoni stresses [18]. Marangoni stresses can, in turn, alter the macroscopic spreading behavior significantly and introduce instabilities at the spreading front. Troian et al. [14] have shown that a capillary ridge appears at the advancing front which is the target of viscous instabilities that lead to a fingering phenomenon. Away from the spreading front, instabilities arising from surfactant concentration or thermal non-uniformities can also give rise to dewetting and hence the formation of dry-spots upon rupture of the liquid film [19, 20].

Future Directions for Research

Despite considerable advances in the investigations carried out on wetting and spreading phenomena over several decades, a complete fundamental understanding is still elusive, particularly at the contact line where significant conceptual and mathematical difficulties arise. Although it has been seen above that the weak logarithmic asymptotic behavior in the contact line region suggests that an intimate knowledge of the microscopic conditions is not required to accurately model the macroscopic spreading behavior, the local microscopic wetting behavior may still be important in many physical systems, and particularly so where nanochannel wetting and transport at molecular scales, are concerned. As such, there is a further need to verify and successively refine our current understanding concerning microscopic wetting dynamics.

This is now possible due to advances in computer processing, which has previously limited the scope of molecular dynamics (MD) simulations in microscopically modeling local dynamic wetting behavior. By integrating the laws of motion governing individual molecular particles and taking into account intermolecular interactions, it is possible to resolve the velocity fields which then provide a mechanism for slippage of liquid molecules over the solid. In addition, dynamic contact angle conditions can be inferred and appear to be dependent on the interaction potentials between the liquid and solid molecules. Nevertheless, MD simulations are still confined to small length scales and continue to be limited to short times. As such, it is envisaged that multi-scale spatial and time averaging techniques will allow a unified coupling between continuum and molecular theories to provide a more complete description for modeling wetting behavior. A description of such multiscale models is given in Karniadakis et al. [21]. MD simulations involving equilibrium statistical mechanics or weak deviations from equilibrium (for example, by means of density-functional theories), can therefore replace the disjoining pressure in molecular theories to explicitly account for intermolecular interactions in an intermediary step in asymptotic matching with continuum hydrodynamic models in the long scale limit.

Zeta-Potential

Definition

The zeta potential ζ is a measure of the electrical charge developed when a solid surface is brought into contact with an aqueous solution. More specifically, when a solid surface is brought into contact with an aqueous solution an electrical charge is generated at the interface. As a result, local free ions in the solution tend to rearrange themselves such that a thin region of non-zero net charge density exists near the interface. The arrangement of the charges at the solid–liquid interface and the balancing counterions in the liquid is usually referred to as the electrical double layer (EDL). There is a thin layer of counterions immediately next to the charged solid surface, called the compact layer. The counterions in the compact layer are immobile due to the strong electrostatic attraction. Counterions outside the compact layer are mobile. This part of the EDL is called the diffuse layer. The zeta potential is the electrostatic potential at the boundary dividing the compact layer and the diffuse layer.

Electrokinetic potential; Surface potential

Definition

►Zeta potential is defined as the electrical potential at the shear plane of the electric double layer. Measurement techniques are based on indirect readings obtained during electrokinetic experiments. Typically, the magnitude of the zeta potential varies between $0 - 200$ mV where both negative and positive values are possible depending on the electrochemistry of the solid-liquid interface.

Overview

►Zeta potential refers to the electrokinetic potential at the shear surface of the electric double layer. Along with surface conductance, zeta potential is an important parameter in the study and modeling of a variety of electrokinetic phenomena relevant to microfluidics and Lab-on-a-Chip devices. The zeta potential of a solid-liquid interface depends on a number of factors including the ion concentration, ion valence, pH level and temperature of the solution. For this reason each solid-liquid interface has its own unique zeta potential that must be measured. Zeta potential measurements are based on indirect readings using one of the following electrokinetic phenomena: electro-osmotic flow, electrophoresis and streaming potential. In terms of microfluidics, electro-osmotic and streaming potential techniques are used in the study of microchannels and capillaries while electrophoresis based methods are used to study charged particles such as fluorescent beads, DNA and proteins.

This document is organized in the following manner: first, a brief introduction to the electric double layer and its significance to electrokinetic phenomenon. Second, the principles behind zeta potential measurements based on the three types of electrokinetic phenomenon are discussed, with special attention to the advantages and disadvantages of each method. Finally, a few key research results for each of the methods are presented. The purpose of this entry is to provide the reader with a brief introduction to the fundamentals of zeta potential measurements, for a more detailed description of zeta potential measurements, electric double layer and electrokinetic phenomenon the reader

should consult the various texts that discuss these topics in depth [1–4].

Basic Methodology

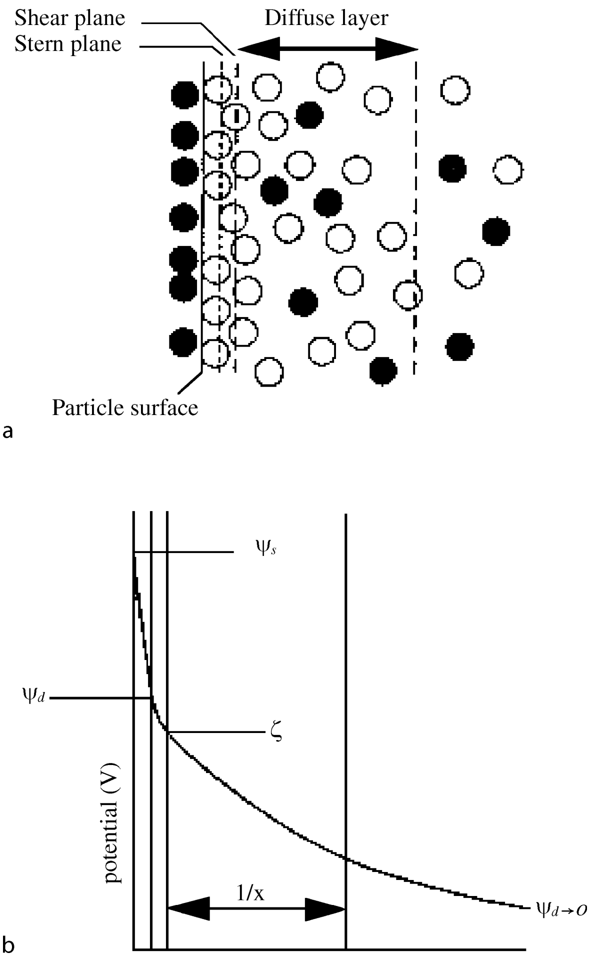
Electric Double Layer and Zeta Potential

In most cases, when a solid surface comes in contact with an aqueous solution an electric charge develops at the interface. The surface charge influences the nearby ions creating a non-uniform electric charge distribution near the interface known as the electric double layer (EDL) [1–4]. Several mechanisms cause this effect including ionization, ion adsorption and ion dissolution.

The earliest theoretical study on the structure of the EDL was performed by Helmholtz (1879) who proposed that the charged interface is surrounded by two condensed planes of oppositely charged ions. In actual fact, thermal forces tend to spread out the ions creating a diffuse region around the interface. Gouy (1910) and Chapman (1913) independently tackled this problem by applying the kinetic molecular theory to the diffuse region of ions. In their model, the electric potential and charge distributions are described using the well-known Poisson–Boltzman equation of statistical physics. Although the model is based on statistical grounds, it produces accurate results when the surface potential is low or the electrolyte concentration is not too high. The major defect of the Gouy–Chapman model is that the ions are treated as point charges; however, in reality ions have a finite size that limits the distance they can approach a surface. Stern (1924) resolved this issue and proposed a new model that divides the EDL into an inner compact layer and an outer diffuse layer. Inside the compact layer the size of the ions is considered while in the diffuse layer the Gouy–Chapman model is still applied.

As shown in Fig. 1, the Stern layer is approximately one ion radius thick and is defined by the solid surface and the Stern plane. Counterions in the Stern layer experience strong electrostatic forces and are essentially immobilized against the surface. Ions located outside the Stern plane experience a weaker electrostatic attraction and form the mobile diffuse layer of the EDL. The boundary separating these two regions is defined as the shear plane. In the diffuse layer, competing electrostatic and thermal forces creates a non-zero concentration of ions that is a maximum at the surface and decreases gradually with distance until it reaches equilibrium with the bulk concentration. The thickness of the diffuse layer is often characterized by the Debye length λ_d which can vary from several nanometers to micrometers depending on the concentration and properties of the solution.

The double layer acts to neutralize the surface charge creating an electrokinetic potential distribution between the



Zeta Potential Measurement, Figure 1 Schematic representation of the electric double layer using Gouy–Chapman–Stern model [3]

interface and the solution. This voltage difference is on the order of millivolts and is refereed to as the surface potential ψ_s. Through the Stern layer the electric potential varies almost linearly to the Stern plane potential ψ_d and then decreases gradually in the diffuse layer until it reaches zero far away from the surface. The electric potential at the shear plane is known as the electrokinetic potential or zeta potential (ζ). Because the zeta potential is located at the fluid flow boundary it is an important parameter for analyzing a variety of electrokinetic phenomenon.

It should be noted that the surface potential and the zeta potential do not always have the same sign [3]. If adsorbed polyvalent or surface active counterions are present the zeta potential may decrease or increase substantially. Thus the zeta potential measurements can not always be extrapolated to determine the surface potential.

In the EDL, the electric potential and net charge density are described by the Poisson–Boltzman equation [1–4].

The Poisson equation describes the electric field within a dielectric medium:

$$\nabla \cdot (\nabla \psi) = \frac{-\rho_e}{\varepsilon_r \varepsilon_0} \quad (1)$$

where ε_0 and ε_r are the dielectric permittivity of a vacuum ($\varepsilon_0 = 8.854 \times 10^{-12}$ C/Vm) and the relative dielectric permittivity of the solution. The net charge density, ρ_e, is the sum of negative and positive ions ($\rho_e = \sum_i z_i e n_i$). Assuming that the Boltzmann distribution is valid, the ionic concentration in the EDL is given by:

$$n_i = n_0 \exp\left(\frac{-z_i e \psi}{k_b T}\right) \quad (2)$$

where n_i is the specific number of the ith ion, n_0 is the number of ions in the bulk solution, z is the valence of the ion, e is the charge of an electron, k_b is Boltzmann's constant and T is the absolute temperature. Combining Eqs. (1, 2) leads to the Poisson–Boltzman equation:

$$\nabla \cdot (\nabla \psi) = \frac{-\sum_i^N z_i e n_0 \exp\left(\frac{-z_i e \psi}{k_b T}\right)}{\varepsilon_r \varepsilon_0} \quad (3)$$

For the special case of a symmetric electrolyte solution ($z : z = 1 : 1$) the Poisson–Boltzman equation reduces to:

$$\nabla \cdot (\nabla \psi) = \frac{2 n_0 z e}{\varepsilon_r \varepsilon_0} \sinh\left(\frac{z e \psi}{k_b T}\right) \quad (4)$$

Applying the non-dimensionalized parameters ($\Psi = ze\psi/kT,\ X = x/L$) to Eq. (4), yields

$$\nabla \cdot (\nabla \Psi) = \kappa^2 L^2 \sinh(\Psi) \quad (5)$$

where κ is the Debye–Hückel parameter and is given by $\kappa = (2z^2 e^2 n_0 / \varepsilon_r \varepsilon_0 k_b T)^{1/2}$. As stated previously, the EDL thickness is characterized by the Debye length ($\lambda_d = 1/\kappa$). For most microfluidic applications involving microchannels the appropriate boundary conditions for solving Eq. (4) are $\psi = \zeta$ at the shear plane and the assumption that $\psi \to 0$ as $x \to \infty$. However, this is not the case for nanochannels where over-lapping boundary layers invalidate the assumption of uniform bulk properties far from the wall. Numerical techniques are usually employed to calculate the electric potential and charge distribution from Eq. (3). Analytical solutions are possible for a few cases where simplified assumptions are justified.

Electrokinetic phenomena arise when the mobile layer of the EDL interacts with an externally applied electric field resulting in relative motion between the solid and liquid phases. There are three types of electrokinetic phenomena relevant to microfluidics: electro-osmotic flow, streaming potential and electrophoresis. In all of these cases, the zeta potential is a key parameter that defines either the fluid flow or particle motion. Since it is not possible to probe the zeta potential directly, measurements are based on indirect readings obtained from electrokinetic experiments. The following discussion focuses on modern methods of measuring the zeta potential using electro-osmotic flow, electrophoresis and streaming potential.

Electro-Osmotic Flow

When an electric field is applied tangentially to the EDL, the mobile ions in the diffuse layer begin to migrate towards the appropriate electrode. Through viscous drag, the motion of the ions causes the surrounding liquid to move generating electro-osmotic flow. The movement also generates an electric current. Since the applied electric field is tangential to the surface, the resulting ion migration does not affect the charge density in the EDL. Thus the body force ($\boldsymbol{F}_b = \rho_e \boldsymbol{E}$) experienced by the fluid is limited to the diffuse layer. Note that it is the external field, $\boldsymbol{E}$, that drives the fluid and not the internal field within the EDL.
The resulting velocity profile is *plug* like, where the velocity is zero at the wall (no-slip condition) and rises to a uniform velocity in the bulk. Since the EDL thickness is very small (~ 30 nm) compared to microchannel (~ 50 μm), to an observer it appears as if the fluid *slips* by the surface. The velocity at the edge of the EDL is given by the classic Helmholtz-Smoluchowski equation:

$$u_{HS} = -\frac{\varepsilon_0 \varepsilon_r \zeta E_x}{\eta} \quad (6)$$

where E_x is the tangential electric field and ζ is the zeta potential. Usually the group of terms, $\varepsilon_0 \varepsilon_r \zeta / \eta$, are combined together into a proportionality constant called the electro-osmotic mobility (μ_{eo}) of the solid-liquid interface. Since the velocity only varies in the EDL, the total flow rate is approximated by $Q = u_{HS} A_c$, where A_c is the cross-sectional area of the microchannel. Thus it is possible to determine the zeta potential by measuring the fluid velocity or volume flow rate under electro-osmotic flow.

Volume Method

One of the earliest methods for determining the zeta potential was to measure the volumetric flow rate of a liquid transported in a capillary under electro-osmotic flow. This method seems simple in principal; however, the small flow rates typical of electro-osmotic flow (~ nl/min) make it

difficult to obtain accurate measurements. Normally the flow rate is determined by following the progression of a meniscus or bubble in an adjoining capillary which in it self produces a variety of errors [2].

Direct Visualization Methods

Several variations of micro flow visualization have been developed for microfluidic applications such as particle-based flow velocimetry and scalar-based flow velocimetry [5]. In terms of the zeta potential measurement, these visualization techniques such as micro-PIV are used to measure the velocity profile and flow rate under electro-osmotic flow. Once the velocity is known the zeta potential can be calculated from Eq. (6). The main advantage of using a flow visualization technique is that the electro-osmotic velocity can be measured directly and in real time. In general, the small amount of particles or dye used has a negligible effect on the electro-osmotic flow being measured. The only significant disadvantage of this technique is that the extent and cost of the hardware may be prohibitive.

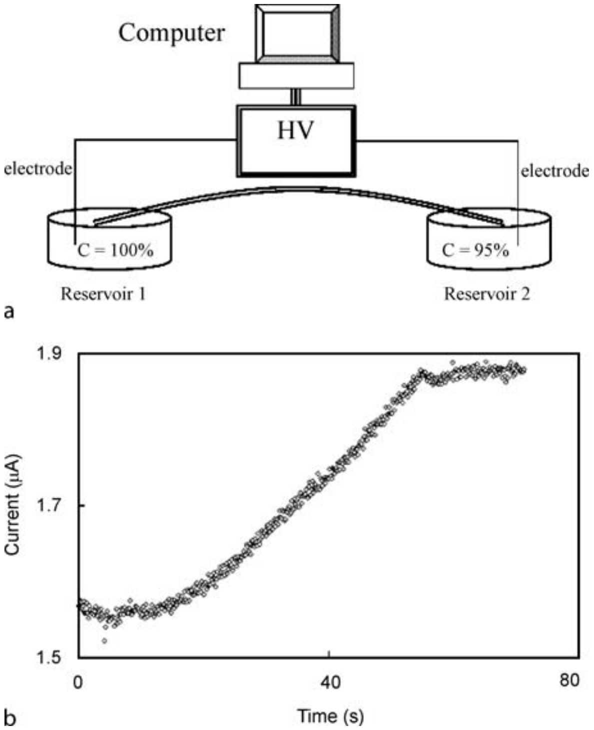
Current-Monitoring Methods

Recently a method has been developed to determine the average flow velocity by measuring the electric current in a microchannel under electro-osmotic flow [6, 7]. The experimental set up is shown in Fig. 2, and consists of a microchannel, a high voltage power supply and a data acquisition system. The microchannel and reservoir 2 are initially filled with an electrolyte solution that has a slightly different concentration than reservoir 1 ($c_1 - c_2 = 5\%$). The concentration difference must be small so that the zeta potential and ionic concentrations are nearly uniform throughout the microchannel.

Immediately after the two solutions are in contact, the high voltage power supply is turned on to induce electro-osmotic flow. As the fluid in reservoir 1 displaces the existing fluid in the microchannel the electric current draw changes. Initially the current is constant and then changes linearly until it reaches another plateau once the initial fluid is completely replaced. The time required for the displacement represents the time required for the solution to travel through the channel length, which can be used to determine the average electro-osmotic velocity:

$$u_{\text{ave}} = \frac{L}{\Delta t} \tag{7}$$

where L is the length of the channel and the zeta potential can be calculated from Eq. (6). The major problem associated with this method is the ambiguity surrounding the



Zeta Potential Measurement, Figure 2 Schematic of the experimental setup for the current-monitoring technique (*a*) and a typical current time plot (*b*) [7]

displacement time. Small current fluctuations and gradual transitions at the beginning and end of the displacement process may cause errors in measuring Δt.

To solve this problem, an improved method was developed to determine the zeta potential by using the slope of the current-time relationship [7]. The slope of the current-time relationship is given as:

$$\text{slope} = \frac{\Delta I}{\Delta t} \tag{8}$$

Under electro-osmotic flow the current in the channel is composed of three parts: 1. the bulk conductivity current, $I_{\text{cond,bulk}}$, the surface conduction current, $I_{\text{cond,surf}}$, and the convection current created by the fluid motion, $I_{\text{cond,conv}}$. Typically, the convection current is several orders of magnitude smaller than the other currents and is neglected. Therefore, the total current is given as:

$$I_{\text{total}} = I_{\text{cond,bulk}} + I_{\text{cond,surf}} = \lambda_b A_c E_x + \lambda_s P_w E_x \tag{9}$$

where λ_b is the bulk conductivity of the fluid, λ_s is the surface conductivity, A_c is the cross-sectional area of the channel, P_w is the wetted perimeter and E_x is the

applied electric field. Substituting Eq. (9) and assuming that $\Delta\lambda_s = 0$, Eq. (8) reduces to:

$$\text{slope} = u_{\text{ave}} \frac{E_x A_c (\lambda_{b2} - \lambda_{b1})}{L} \quad (10)$$

The above expression can then be rearranged to solve for u_{ave} and then substituted into Eq. (6) to calculate the zeta potential. In addition, the surface conductivity can be measured using this method. In this case, the reservoirs are filled with the same fluid and the total current is measured. The surface conductivity is calculated from Eq. (9) assuming that the bulk conductivity is already known.

The disadvantages of the current monitoring technique are that

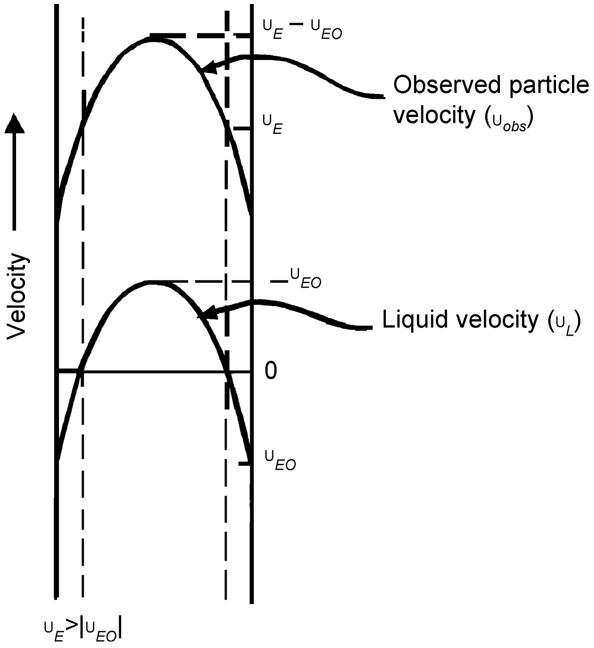
- the electro-osmotic flow is measured indirectly through the current draw,
- the method assumes constant zeta potential between the two fluids,
- the difference in conductivity must be large enough so that the current change is measurable, and
- there is a lack of spatial and temporal resolution since the zeta potential represents an average value.

The advantage of using this method is in its simplicity, current-time measurements can be performed quickly and with relatively little infrastructure compared to other methods.

It should be noted that there are several additional sources of error for electro-osmotic based measurements. Joule heating must be controlled or temperature fluctuations may cause significant changes in zeta potential, viscosity and other fluid properties. Another source for error is undesired pressure driven flow caused by small head and meniscus (Laplace pressure) differences at the reservoirs. In fact, even modest differences ($\sim$ 5 mm of head) can lead to pressure driven flow rates comparable to the electro-osmotic flow being studied. Also electrolysis occurring at the electrodes may create a pH gradient along the channel creating significant errors in the zeta potential measurement. On the other hand, electro-osmotic flow and electro-osmotic pumping are common methods of transporting fluids in microfluidic devices. Therefore, zeta potential measurements based on electro-osmotic flow provide the most accurate representation of on-chip operating conditions.

Electrophoresis

Electrophoresis refers to the movement of a charged surface relative to a stationary liquid. For instances, under an applied electric field a negatively charged particle will migrate towards the positive electrode (anode).



Zeta Potential Measurement, Figure 3 Stationary level, fluid velocity and particle velocity distribution in an electrophoresis cell [1]

For spherical particles the velocity is given as [1]:

$$u_E = \mu_{ep} \boldsymbol{E} \quad (11)$$

where μ_{ep} is called the electrophoretic mobility of the particle. The electrophoretic mobility is related to the zeta potential through:

$$\mu_{ep} = \frac{2\varepsilon_0\varepsilon_r\zeta}{3\eta} f_1(\kappa a) \quad (12)$$

where a is the radius of the particle, η is the viscosity of the liquid, κ is the Debye–Hückel parameter and $f_1(\kappa a)$ is a correcting function that depends on the shape of the particle. Therefore the zeta potential can be calculated from Eq. (12) if the electrophoretic mobility is known.

The most popular method of measuring electrophoretic mobility is micro-electrophoresis. In micro-electrophoresis, particles are placed in a closed capillary with electrodes at either end. When an electric field is applied the particles migrate towards the electrode and their velocities are measured. Because the capillary walls are charged the applied electric field will also induce an electro-osmotic flow. However, since the capillary is closed a back pressure creates a net zero flow in the tube (see Fig. 3). The particle velocity is a combination of the electrophoretic motion and the fluid flow. To obtain the true electrophoretic mobility the particles must be tracked along the stationary layer where the fluid velocity is zero.

Z

For a circular capillary the liquid velocity across the tube is given by the electro-osmotic flow and the back pressure flow:

$$u = u_{EO} + u_{BP} \tag{13}$$

For a pressure driven flow the velocity profile is given by the solution of the Poiseuille equation ($u_{BP} = -c(a^2 - r^2)$), where c is a constant. The value of c is determined by realizing that the net flow in the capillary is zero, $c = 2u_{EOF}/a^2$. The velocity profile is then given by:

$$\frac{u}{u_{EOF}} = 2\frac{r^2}{a^2} - 1 \tag{14}$$

The stationary level is determined by setting u to zero so that $r_{stat} = a/\sqrt{2}$. The same procedure repeated for a plane cell results in $y_{stat} = a(1 - 1/\sqrt{2})$. Since the velocity varies significantly across the capillary, locating the stationary level is critical for obtaining accurate results.

Early methods of measuring the particle velocities involved manually tracking them along a reference grid using a microscope. This process was tedious and not very accurate since only a few particles could be tracked at a time. Modern devices use a variety of measurement techniques to increase the accuracy and throughput of the procedure. Current devices use laser Doppler velocimetry (LDV) and phase analysis light scattering (PALS) to measure particle velocity. New developments focus on suppressing electro-osmotic flow through surface modifications of the capillary or by using oscillating electric fields to take advantage of time scale differences between electrophoresis and electro-osmotic flow. It should be noted that electrophoresis is also used as a method of separating charged particles such as proteins and DNA in a variety of biomedical applications. A few examples include gel electrophoresis, isoelectric focusing and capillary zone electrophoresis.

Streaming Potential

If an electrolyte solution is forced through a microchannel under pressure driven flow, charges in the EDL move downstream resulting in an electric current called the streaming current:

$$\boldsymbol{I}_s = \int_v \boldsymbol{u}\rho_e \, dv \tag{15}$$

where $\boldsymbol{I}_s$ is the streaming current, $\boldsymbol{u}$ is the velocity and ρ_e is the net charge density. The accumulation of these charges creates a potential difference across the channel known as the streaming potential. This potential, in turn, drives the conduction current in the opposite direction of the streaming current. The conduction current is the sum of the bulk and surface conduction:

$$\boldsymbol{I}_c = A_c \boldsymbol{E}_s \lambda_b + P_w \boldsymbol{E}_s \lambda_s \tag{16}$$

where $\boldsymbol{I}_c$ is the conduction current, A_c is the cross-sectional area, $\vec{E}_s$ is the streaming potential electric field, P_w is the wetting perimeter, λ_b and λ_s are the bulk and surface conductivities, respectively. At steady state, $\boldsymbol{I}_c + \boldsymbol{I}_s = 0$ and the general relationship between the streaming potential and *zeta potential* can be derived as:

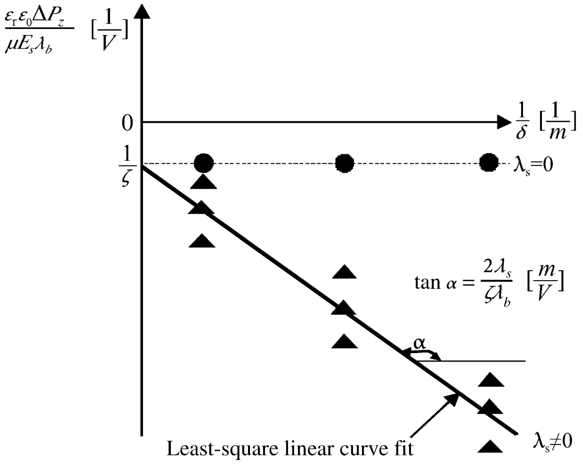
$$\frac{\boldsymbol{E}_s}{\Delta P} = \frac{\varepsilon_0 \varepsilon_r \zeta}{\eta(\lambda_b + f\lambda_s)} \tag{17}$$

where ΔP is the pressure difference, f is a shape factor for the channel and is given as the ratio of the wetted perimeter to the cross-sectional area ($f = P_w/A_c$). One can see that Eq. (17) provides a basis for calculating the zeta potential and surface conductance if the pressure drop and streaming potential are measured. By rearranging Eq. (17) a more convenient form of the streaming potential equation appears:

$$\frac{\Delta P \varepsilon_0 \varepsilon_r}{\eta \boldsymbol{E}_s \lambda_b} = \frac{1}{\zeta} + \left(\frac{2\lambda_s}{\zeta \lambda_b}\right) f \tag{18}$$

For a physical system λ_s and ζ should remain constant. Eq. (18) shows that there is a linear relationship between the streaming potential measurement and the form factor as shown in Fig. 4. The zeta potential is calculated from the intercept and the surface conductivity from the slope. Therefore, unless the surface conduction is neglected at least two measurements are required to determine the zeta potential and surface conductivity. For practical purposes multiple streaming potential experiments are performed for different form factors to increase the accuracy of the measurements.

A typical experimental apparatus consists of a capillary connected to a pump through a pipe network and a series of transducers strategically placed to measure the pressure drop, flow rate, streaming potential and conductivity. The piping network is designed so that the flow direction can be reversed in the microchannel. Particular attention is required in the preparation and assembly of the apparatus. The potential must be measured with a high impedance electrometer so that the streaming current and therefore the flow in the microchannel are not disturbed. Also, it is important to use electrodes that respond reversibly to current flows (eg. Ag/AgCl).



Zeta Potential Measurement, Figure 4 Plot of the relationship between streaming potential, surface conductance and zeta potential used in the streaming potential method [8]

To prevent the electrodes from polarization streaming potential measurements must not exceed 1 – 2 minutes before the flow should be reversed and measurements taken again. By reversing the flow any errors caused by the asymmetry of the electrode system are also reduced. For a given gap height this procedure should be repeated for several different flow rates. Consequently, in order to obtain an accurate streaming potential plot a number of experiments (~ 20) must be performed.

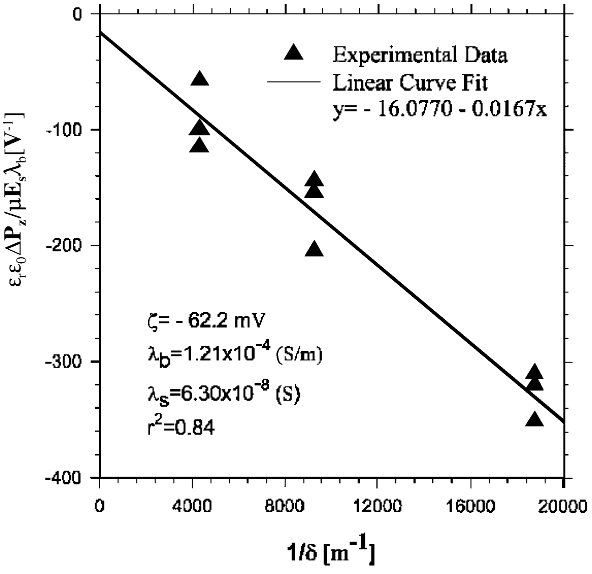
It is important to emphasize the need to measure the surface conductance as well as the zeta potential. If the surface conductance is neglected in Eq. (18) the zeta potential can be severely underestimated. It should also be noted that the equations derived above neglect electrokinetic effects on the flow by assuming a Poiseuille type flow through the microchannel. In actuality the streaming potential creates a reverse electro-osmotic flow in the channel that decreases the overall flow rate. The decreased velocity creates the appearance of an increased fluid viscosity and is known as the electroviscous effect. Generally this effect is prevalent in microchannels less than 50 μm.

Key Research Findings

Sanders et al. applied the micro-electrophoresis technique to measure the zeta potential of finely ground glass slides as a function of pH [9]. The results show that for glass particles suspended in a 0.1 M NaCl the zeta potential varies from −20 mV for a pH of 3 to −75 mV for a pH of 10 demonstrating the importance of pH on zeta potential. One problem that arises with this method is whether the zeta potential measured using finely crushed particles corresponds to the zeta potential of the uncrushed solid-liquid interface. The act of grinding may alter the zeta potential of the original material and is still a topic of debate.

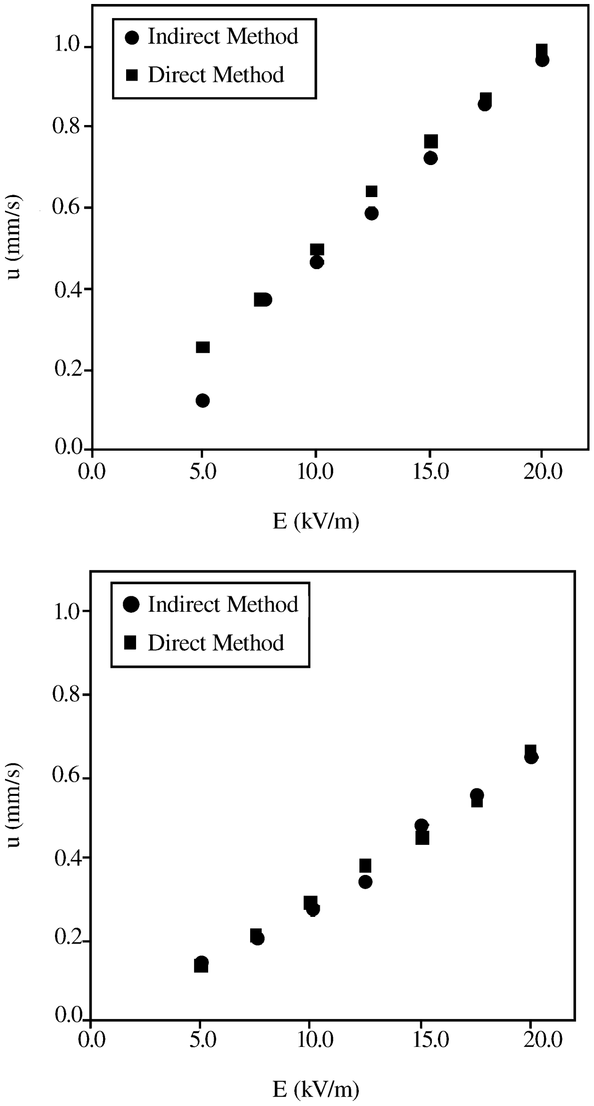
Oddy and Santiago used micro-PIV techniques to study small particles in AC and DC electro-osmotic flow [10]. Independent measurements of the particle motion in the two fields can be correlated to determine the electrophoretic mobility of the particle and electro-osmotic mobility of the solid-liquid interface. The electrophoretic mobility of the fluorescent polystyrene particles was found to be -3.76 ± 0.05 μm cm/Vs and the zeta potential of the glass/water interface for a pH of 7 was -115 ± 10 mV.

Gu and Li [8] used the streaming potential method to study the effects of surface conductance, pH, ionic concentrations and surfactants on zeta potential using the streaming potential technique. A glass slit microchannel was used as the capillary which has a form factor of $f = 1/\delta$, where δ is the gap height. As an example, the streaming potential plot obtained for deionized ultrafiltered (DIUF) water is shown in Fig. 5. Each data point represents the average of 18 readings for a given flow rate and for each gap height three flow rates were studied. Ideally for a given gap height the results for different flow rates should be almost identical. The discrepancy is attributed to the fact that the measured streaming potential $\boldsymbol{E}_S$ is not exactly proportional to the pressure drop ΔP as specified in Eq. (18). A least-square linear curve fit of the data determines the zeta potential and surface conduction. In particular, the zeta potential for a glass-water interface was determined to be -62.2 mV and -22.7 mV for an electrolyte solution of 1×10^{-3} M NaCl solution. In addition, for glass/water the zeta potential var-



Zeta Potential Measurement, Figure 5 Experimental data from streaming potential measurements for glass/DIUF water in a slit microchannel [8]

Z



Zeta Potential Measurement, Figure 6 Plot of the electro-osmotic velocity as a function of the applied electric field for two buffers (*a*) 1xTAE and (*b*) 1xTBE. Results for both the direct flow visualization method and the current-monitoring method are shown [6]

ied from −40 mV for a pH of 3 to −80 mV for a pH of 10. Sinton et al. [6] utilized both the direct visualization method and current monitoring technique to measure the zeta potential for two buffer solutions commonly used in biochemistry. The direct method employed caged fluorescent dye that upon exposure to an intense ultraviolet light uncages and fluoresces. The fluorescent dye is then tracked through a series of images that are analyzed to determine the velocity field. Electro-osmotic velocity measurements for the two methods are shown in Fig. 6. The results from both methods are in excellent agreement indicating that the simpler current-monitoring method produces accurate measurements.

Future Directions for Research

Zeta potential is a fundamental parameter for modelling and characterizing electrokinetic flows in a variety of microfluidics and Lab-on-a-Chip devices. Because the zeta potential depends on so many factors (pH, concentration, liquid, surface etc.) more measurements are required for a variety of surface-liquid combinations; particularly, biological and biochemical fluids. Since measurements can vary greatly between methods and experiments, multiple tests should be employed to accurately determine the zeta potential. In addition, measurements performed using multiple techniques can be corroborated which will reduce errors between results. The ultimate goal is to develop an accurate database of zeta potential measurements for various solid-liquid interfaces, however this will most likely require the development of new theoretical models and experimental methods to increase the accuracy and throughput of current devices.
